Received 16 April 1998/Accepted 24 July 1998

To evaluate the persistence of PCR-detectable Bacteroides distasonis in surface water, whole human feces were dispersed into water from the Ohio River and incubated in flasks in the laboratory or in diffusion chambers in situ. Duplicate samples were taken daily, and material that pelleted at 16,000 × g was assayed by PCR. Persistence of PCR-detectable DNA from this anaerobe depended upon temperature and predation, two of the factors shown by others to influence the survival of aerobic bacteria detected by culture. B. distasonis was detected by PCR for at least 2 weeks at 4°C but for only 4 to 5 days at 14°C, 1 to 2 days at 24°C, and 1 day at 30°C. In filtered water or in the presence of cycloheximide, a eukaryotic inhibitor, persistence at 24°C was extended by at least a week.

Because fecal coliform bacteria can survive and grow in some surface waters (1, 12), their presence cannot be used to pinpoint the source of fecal pollution. It has been suggested that enteric anaerobes, such as the Bacteroides spp., might be better indicators because they survive for only a few hours in oxygenated waters (3, 13). However, the need to maintain anaerobic conditions during cultivation and identification by classical methods discourages the use of anaerobes for routine monitoring. An assay based on specific nucleic acid detection would circumvent the need to cultivate. Recently, I reported PCR-based assays to detect three of the dominant Bacteroides species from the human colon and suggested that this technique might be used to monitor fecal pollution in water (7). However, because PCR can detect DNA in dead bacteria, as well as in living and severely stressed organisms (6), the persistence of PCR-detectable bacteria in the environment must be evaluated.

To investigate the persistence of PCR-detectable Bacteroides distasonis in surface water, whole human feces were dispersed in water collected from the Ohio River and incubated in situ or in the laboratory. Feces, rather than a pure culture, were used as the source of B. distasonis because fecal organisms are the intended target. Fecal bacteria are likely to differ physiologically from cultured organisms, and other fecal components may affect persistence. Preliminary experiments showed that 10 μg of feces/ml of river water was needed for strong detection of B. distasonis with 1-ml samples, 10% of which was analyzed by PCR. This level was at least 10-fold greater than the detection limit, defined as the level at which B. distasonis was detected consistently. In previous experiments, endogenous B. distasonis was detected consistently in Ohio River water by PCR (Fig. 2 of reference 8; data not shown). However, in the present study, 200-fold less river water was analyzed, and as a result, this background level was below the detection limit.

To add feces to river water, 1 g of fresh feces was dispersed thoroughly in 100 ml of sterile deionized water in the labora-
Experiments ran from 24 to 29 April (rows a and b), from 5 to 10 May (rows c and d), from 6 to 11 June (rows e to h), and from 6 to 13 July (rows i to l), all in 1995. Surface water temperatures in the river were 14, 14, 22 to 24, and 26 to 28°C, respectively. Rows a, b, e, f, i, and j are samples taken from diffusion chambers incubated in the river. Rows c, d, g, h, k, and l are samples from flasks incubated in the laboratory at the indicated temperatures.

FIG. 1. Seasonal variation in persistence in situ and in the laboratory. Feces were dispersed in raw river water, duplicate 30-ml portions were incubated in diffusion chambers in the river or in flasks in the laboratory, and daily samples were assayed for the presence of *B. distasonis* by PCR and dot blot hybridization as described in the text. Samples were taken before addition of feces, immediately after addition of feces (day 0), and after incubation for 1 to 5 days. Experiments ran from 24 to 29 April (rows a and b), from 5 to 10 May (rows c and d), from 6 to 11 June (rows e to h), and from 6 to 13 July (rows i to l), all in 1995. Surface water temperatures in the river were 14, 14, 22 to 24, and 26 to 28°C, respectively. Rows a, b, e, f, i, and j are samples taken from diffusion chambers incubated in the river. Rows c, d, g, h, k, and l are samples from flasks incubated in the laboratory at the indicated temperatures.

To verify that temperature influences the persistence of PCR-detectable *Bacteroides*, feces were dispersed in Ohio River water collected in early May 1995, when the surface temperature was 14°C, and again in mid-July 1995, when the surface temperature was 30°C. On both occasions, the water containing feces was incubated at 4, 14, 24, and 30°C in the laboratory. Results of the July experiment are shown in Fig. 2: those for May were very similar. While at 4°C, PCR-detectable *B. distasonis* persisted for the full 14 days of the experiment (Fig. 2, rows a and b). *B. distasonis* was detected for only 5 to 6 days at 14°C (rows c and d), for 1 to 2 days at 24°C (rows e and f), and for 1 day at 30°C (rows g and h). In May, *B. distasonis* was detected for 1 day longer at 14°C than shown for the July experiment. Therefore, persistence was inversely related to incubation temperature and varied over 10-fold between 4 and 30°C, regardless of whether the source water temperature was at 14 or 30°C.

While temperature strongly influences the rate of degradative processes, it also affects the activity of predators. To determine if predation played a role in the loss of PCR-detectable *Bacteroides*, Ohio River water was filtered to remove organisms larger than 0.45 µm before feces were added to one pair of flasks, and cycloheximide (250 µg/ml; reference 15) was added to raw water to inhibit eukaryotes before addition of feces to a second pair of flasks. As shown in Fig. 2 (rows i and j), *B. distasonis* was detected for at least 14 days in filtered river water at 24°C, at least 12 days longer than in raw water. Similarly, *B. distasonis* was detected for at least 10 to 12 days in raw water containing cycloheximide (which had been dissolved in absolute ethanol; Fig. 2, rows m and n), over a week longer than in raw water containing solvent only (ethanol; Fig. 2, rows k and l). Therefore, elimination of PCR-detectable *B. distasonis* was due, at least in part, to predation by eukaryotes. Since cycloheximide does not completely inhibit all eukaryotes (14, 16, 17), the difference between persistence of PCR-detectable *Bacteroides* in filtered versus cycloheximide-treated water may be due to residual grazing by protists, as well as to the activity of prokaryotes and, perhaps, to interaction with materials larger than 0.45 µm.

The results of this study show that persistence of PCR-detectable DNA from an anaerobic bacterium, *B. distasonis*, is influenced by temperature and predation, as has been reported for survival of aerobic bacteria detected by culture (4, 5, 10, 12, 15). Although PCR detects dead as well as living bacteria, while culture does not, this distinction is less important at temperatures at which predators are active and eliminate both targets. Other investigators have also reported rapid loss of PCR-detectable bacteria introduced into natural waters collected during summer months (2, 9). However, at low temperatures, at which predators and degradative processes are less active, the PCR target is preserved for an extended time. As a consequence, seasonal variation in persistence must be considered, as with traditional monitoring approaches.

I thank Robert Safferman of the U.S. Environmental Protection Agency for encouraging and supporting these studies.

This research was supported in part by an appointment to the Postgraduate Research Participation Program administered by the Oak Ridge Institute for Science and Education through an interagency agreement between the U.S. DOE and the U.S. EPA.
