When metals were added in a pulse mode to methylotrophic-methanogenic biomass, three methane production rate phases were recognized. Increased concentrations of Ni and Co accelerated the initial exponential and final arithmetic increases in the methane production rate and reduced the temporary decrease in the rate. When Ni and Co were added continuously, the temporary decrease phase was eliminated and the exponential production rate increased. We hypothesize that the temporary decrease in the methane production rate and the final arithmetic increase in the methane production rate were due to micronutrient limitations and that the precipitation-dissolution kinetics of metal sulfides may play a key role in the bioavailability of these compounds.

Previous research (7, 19, 25, 27) has shown that metal deficiencies can limit the performance of anaerobic digestion systems and that metal supplementation may substantially improve the performance of such systems. In particular, the benefits of nutrient supplements during methanization of industrial wastewaters have been recognized (26, 27).

Methanogenesis from methanol is known to proceed by the following pathways: (i) methanol can be directly converted to methane by methylo trophs; (ii) methanol can be converted to bicarbonate by aceticlastic methanogens, and (iii) methanol can be converted to hydrogenophilic methanogens and/or acetogens to form methane and acetate, respectively (7). Methanosarcina type bacteria are responsible for direct conversion of methanol to methane, and Ni, Co, and Fe are components of the enzymes that catalyze many of the reactions of this methylotrophic pathway (4, 5, 10, 12, 28). It has been reported that metal supplementation may substantially improve anaerobic treatment of different types of waste streams (8, 9, 20, 27). However, the previously described metal additions that are optimal vary by several orders of magnitude (29). Furthermore, previously published information concerning the relationship between kinetic data and “optimum” metal concentrations is rather unclear. This is illustrated by the fact that for similar batch systems, the metal (Ni or Co) doses can vary from 0 to 40 μM (16, 21–23).

Since methanol-consuming methanogens have specific trace metal requirements and since many industrial waste streams contain methanol as an important contaminant, in the present study we examined the kinetics of methanol consumption by methanogenic biomass in the presence of different Ni and Co concentrations.

Anaerobic granular sludge from a full-scale expanded granular sludge bed, a Biobed EGSB reactor (location, Caldic Europort) developed by Biothane Systems (Delft, The Netherlands), was used. The sludge treated wastewater generated during production of formaldehyde. The waste stream contained primarily methanol and formaldehyde as organic substrates (30). To prevent mass transfer limitations, the granular structure was disrupted with a blender, and the sludge suspension obtained was used as the inoculum. The initial concentration of the inoculum expressed as the amount of volatile suspended solids (VSS) in the reactor, was 1.5 g liter⁻¹. The standard medium used contained the following components: 15 mM NH₄Cl, 7 mM KH₂PO₄, 4 mM MgSO₄, 5 mM CaCl₂, and 35.74 mM NaHCO₃. This medium also contained yeast extract (100 mg/liter) and trace elements, which were present at the following concentrations: H₃BO₃, 4.03 μM; ZnCl₂, 1.84 μM; CuCl₂, 1.11 μM; MnCl₂, 12.63 μM; (NH₄)₆Mo₇O₂₄, 0.2 μM; AlCl₃, 1.86 μM; Na₂SeO₃, 3.12 μM; and FeCl₂, 50 μM. Ni and Co were added as NiCl₂ and CoCl₂, respectively, at the concentrations indicated below. Methanol was used as the carbon source at an initial concentration of 208 mM (10 g of chemical oxygen demand [COD] per liter). The pH in each reactor during the experimental period was 7 to 7.2. All chemicals were analytical grade, and most chemicals were purchased from Merck (Darmstadt, Germany); yeast extract was purchased from Oxoid Unipath Ltd. (Hampshire, England).

The reactors used were completely stirred plastic vessels. They were filled with 2.5 liters of mineral medium and flushed with a 70% N₂–30% CO₂ mixture for 20 min, after which Na₂S · 8H₂O was added to a final concentration of 0.54 mM; finally, Ni and/or Co was added. After a 24-h period, in which we assumed that chemical equilibrium was established, the inoculum and methanol were added. The reactors were operated in batch mode in a temperature-controlled (30 ± 1°C) room. The biogas produced was passed through an Erlenmeyer flask filled with a 20% NaOH solution and then through a tube filled with soda lime pellets with thymol blue indicator. Finally, the gas was passed through a Mariotte flask system containing water for quantification of methane production. The methane produced was monitored continuously by measuring the weight of the displaced water with a pressure sensor (model QB 745; DS-Europe) connected to a programmable data logger system (model CR10; Campbell). The data were recorded every 10 s and were averaged over a 30-min interval. A personal computer programmed to function as a terminal emulator was used.
methane formation through acetate or H2-CO2 did not play an
important role. Hence, experiments with different Co and Ni additions
were performed.

Either Ni or Co was added at a concentrations of 0, 4, 40,
and 400 μM, while the other metal was added at a concentra-
tion of 40 μM. All of the curves showed that there was a
decrease in the methane production rate after approximately
40 h (Fig. 2A and B). However, as the concentration of Co
increased, the size of the temporary decrease in the methane
production rate decreased and the slope of the arithmetic
increase became greater (Fig. 2A). On the other hand, nickel
concentrations of 4 and 40 μM increased the methane produc-
tion rate during phase I (Fig. 2B). Furthermore, it seemed that
nickel affected phase I most, whereas cobalt affected phase III
most. However, in contrast to the cobalt experiments, addition
of 400 μM nickel was inhibitory.

Additions containing Ni plus Co were also tested. These
micronutrients were simultaneously added at concentrations
of 0, 1, 4, and 40 μM each. As in the previous experiments, the
metals were added 24 h prior to inoculation. The results (Fig.
2C) clearly demonstrated that metal bioavailability was limited
since as the amount of metal increased, the exponential growth
during phase I increased, the temporary decrease in phase II
was less pronounced, and the arithmetic rate of increase during
phase III was faster. However, the observed limitations were
not completely eliminated even with metals concentrations as
high as 40 μM Ni and 40 μM Co. Therefore, continuous
addition of the metals was tested to see whether micronutri-
ent limitations could be overcome.

Co and Ni were added continuously at rates of 0, 0.05, 0.2,
and 2 μmol h⁻¹; hence, the concentrations in the reactor after
50 h of addition or an 80-h experimental period (the first doses
were added after 30 h) were 0, 1, 4, and 40 μM, respectively.
The results of this test are shown in Fig. 2D.

Doses of 0.05 and 0.2 μmol h⁻¹ (1 and 4 μM, respectively)
seemed to elimate limitations, and the previously observed
decrease in the methane production rate during phase II was
not observed in these experiments. Also, the period of ex-
ponential increases in the methane production rate was extended.
However, a dose of 2 μmol h⁻¹ (40 μM) appeared to be
inhibitory.

Rate curves having the shape shown in Fig. 1 and 2A to C
can reflect either (i) limitations due to substrate or nutrient
depletion or (ii) production of a toxic compound. The tempo-
rary decrease in the methane production rate could not be
attributed to substrate limitations since in all cases the meth-
anol concentration at 40 h was more than 3,000 mg of COD
liter⁻¹ and the reported apparent substrate affinity coefficient
(Ks) for methylotrophic methanogens was 12 mg of COD li-
ter⁻¹ (6). Possible limitations due to the production of form-
aldehyde, which is a toxic compound and an intermediate (at
the oxidation level) during the oxidation of methanol (10),
were not detected. Furthermore, the limitations could not be
attributed to macronutrient limitations since in separate ex-
periments performed with different amounts of macronutrients
the methane production rate was not affected (data not shown).

**Spiked addition of metals.** The results of this work clearly
show that the biomass was nickel and cobalt limited. Two main
theoretical aspects should be considered in order to under-
stand the limitations observed. (i) Assuming that Methanosar-
cina barkeri Fusaro cells grown on methanol contained 0.135
and 0.06 mg of Ni and Co per g of cells, respectively (18),
and that the yield was 0.088 g of cells/g of methanol COD (23),
then 2 μM Ni and 0.89 μM Co would be required for conver-
sion of the 10 g of methanol COD liter⁻¹ added in the exper-
iments (Table 1). According to this reasoning, addition of more than 2 μM metal should fulfill the nutrient requirements. However, as the spiked dose experiments showed, this was not the case, and the metals added (>2 μM) seemed to be not available for biomass since limitations were still observed. (ii) If it is assumed that there is chemical equilibrium, then the following trends can be expected: the calculated concentrations of free Ni and Co should increase sharply only when the initial dose of Ni and the initial dose of Co are more than 100 μM, corresponding to the moment that the amount of sulfide added becomes limiting for precipitation reactions (Fig. 3). Although metal sulfide complexes may be important soluble species at pH values greater than 7 (15), at metal concentrations below 100 μM the concentrations of dissolved metals that occur as (i) free metals (M{sup 2+}), as well as and the concentrations of (ii) free metal plus sulfide complexes (MHS{sup -}), should be less than 0.01 and 0.05 μM, respectively (Fig. 3). If dissolution of the precipitated metals were negligible, these concentrations of dissolved metals would not fulfill the nutrient requirements, as indicated in Table 1. Therefore, we concluded that metal shortage must have been compensated for by dissolution of precipitated metal sulfides.

Based on these considerations, the general trend in the

<sup>a</sup> In general, during phase I approximately 3 to 6 g of COD methanol per g of cells is consumed.

<sup>b</sup> Value calculated by using the cell metal composition reported by Scherer et al. (18) and by assuming that the yield was 4.23 g of cells/mol of methanol (0.088 g of cells/g of COD), as described by Silveira et al. (22).

<sup>c</sup> Experimental value reported by Nishio et al. (17).

FIG. 2. Methane production rate curves obtained with methanol. (A) Different initial Co concentrations. In all cases Ni was added at a concentration of 40 μM. (B) Different initial Ni concentrations. In all cases Co was added at a concentration of 40 μM. (C) Different Ni and Co concentrations added simultaneously. (D) Continuous addition of Ni and Co during methanol degradation. Different rates of addition were tested. The arrow indicates when the metals were first added. The rates at which the metals were added were 0 μmol h<sup>−1</sup> (line a), 0.05 μmol h<sup>−1</sup> (line b), 0.2 μmol h<sup>−1</sup> (line c), and 2 μmol h<sup>−1</sup> (line d).

FIG. 3. Calculated equilibrium dissolved metal concentrations with different initial doses of Ni and Co.
methane production rate (Fig. 1) can be explained as follows. During the first 30 to 40 h of the process (phase I), readily dissolved precipitates provide the required nutrients, which results in an exponential increase in the methane production rate of the methylo trophic population. However, if the metal uptake rate is higher than the rate of dissolution, then metal-limited conditions for the bacteria prevail. This situation occurred during phase III, when the growth rate increased arithmetically; this increase was determined by the rate of dissolution of metal sulfides. The temporary decrease in the methane production rate (phase II) may have been due to severe metal limitation that was even greater than that in phase III, suggesting that in addition to bacterial growth the specific methane conversion rate is affected by limiting concentrations of Co and/or Ni. It should be noted that different types of precipitates of the same metal can be present in a system (some compounds dissolve faster than others) and that the dissolution rate of a specific metal sulfide may not be constant since it depends on the total surface area.

Continuous addition of metals. Nutrient limitations can be overcome if the essential metals are added continuously at a proper rate so that their availabilities in solution can fulfill the requirement for biomass activity and growth. The results obtained in the continuous addition experiments clearly show this effect and thus indicate the importance of the dissolution rate kinetics of metal sulfide precipitates in anaerobic digestion processes.

When the metals were added continuously at a rates of 0.05 to 0.2 µmol h⁻¹, the temporary decrease in the methane production rate was eliminated and the period of exponential production was extended (Fig. 2D). These rates of addition corresponded to metal concentrations of 1 to 4 µM and agree well with the calculated metal requirements based on the biomass yield and Ni and Co contents of biomass (Table 1) for Methanosarcina spp. grown on methanol. Other studies have also shown that when essential nutrients are added continuously in fed batch systems, the period of exponential growth of M. barkeri is drastically extended compared to a system in which nutrients are added in one dose (17). Thus, when the amount of substrate is not limiting, metal dissolution might become the rate-limiting step.

Practical implications. During operation of a continuous reactor, less metal may be required than the amount required in a batch system, because more biological ligands may be produced (3, 13, 14) and because continuous addition of nutrients ensures free metal availability for biomass uptake. In practice, in view of the clear evidence that supplying metal enhances the treatment of several effluents, there is a tendency to add nutrients in excessive amounts. This could lead to inhibitory effects on the biomass and/or to metal accumulation in the sludge. Hence, in order to determine a more rational way to add essential metals, studies to understand the process kinetics of precipitation and dissolution in anaerobic systems in combination with the kinetics of nutrient uptake by the microorganisms are necessary. In this paper we show that a rational supply of metals can be achieved, which in turn may open the possibility of either enhancing or diminishing the production of biomass depending on the treatment and remediation needs.

On-line CH₄ monitoring. With on-line measurements of methane production very detailed kinetic information can be obtained. To our knowledge, there are no previous reports of kinetic data being analyzed by on-line measurement of the CH₄ production rate. Furthermore, the informative value of the results can be maximized when rate-time curves are plotted instead of cumulative curves for CH₄ production. Accurate rate data can be obtained only by on-line measurement. The observed decrease and subsequent increase in the rate (Fig. 1, phase II) would have been overlooked with cumulative plots or may have been treated as an analytical error.

Finally, although kinetic data are commonly assessed by assuming that only carbon is limited, discrepancies in previously reported kinetic constants could be due to nutrient limitations in batch experiments, as shown in this study. This suggests that straightforward comparisons of previously published kinetic parameter data are not possible.

We thank Merle de Kreuk for help during experimental work and Herman van Leeuwen and Jim Field for valuable discussions.
