Received 1 March 1999/ Accepted 23 May 1999

Earthworms (Aporrectodea caliginosa, Lumbricus rubellus, and Octolasion lacteum) obtained from nitrous oxide (N\textsubscript{2}O)-emitting garden soils emitted 0.14 to 0.87 nmol of N\textsubscript{2}O h\textsuperscript{-1} g\textsuperscript{-1} (fresh weight)\textsuperscript{-1} under in vivo conditions. L. rubellus obtained from N\textsubscript{2}O-emitting forest soil also emitted N\textsubscript{2}O, which confirmed previous observations (G. R. Karsten and H. L. Drake, Appl. Environ. Microbiol. 63:1878–1882, 1997). In contrast, commercially obtained Lumbricus terrestris did not emit N\textsubscript{2}O; however, such worms emitted N\textsubscript{2}O when they were fed (i.e., preincubated) in garden soils. A. caliginosa, L. rubellus, and O. lacteum substantially increased the rates of N\textsubscript{2}O emission of garden soil columns and microcosms. Extrapolation of the data to in situ conditions indicated that N\textsubscript{2}O emission by earthworms accounted for approximately 33% of the N\textsubscript{2}O emitted by garden soils. In vivo emission of N\textsubscript{2}O by earthworms obtained from both garden and forest soils was greatly stimulated when worms were moistened with sterile solutions of nitrate or nitrite; in contrast, ammonium did not stimulate in vivo emission of N\textsubscript{2}O. In the presence of nitrate, acetylene increased the N\textsubscript{2}O emission rates of earthworms; in contrast, in the presence of nitrite, acetylene had little or no effect on emission of N\textsubscript{2}O. In vivo emission of N\textsubscript{2}O by earthworms was greatly stimulated when worms were preincubated in soil supplemented with streptomycin and tetracycline. On a fresh weight basis, the rates of N\textsubscript{2}O emission of dissected earthworm gut sections were substantially higher than the rates of N\textsubscript{2}O emission of dissected worms lacking gut sections, indicating that N\textsubscript{2}O production occurred in the gut rather than on the worm surface. In contrast to living earthworms and gut sections that produced N\textsubscript{2}O under anaerobic conditions (i.e., in the presence of air), fresh casts (feces) from N\textsubscript{2}O-emitting earthworms produced N\textsubscript{2}O only under anaerobic conditions. Collectively, these results indicate that gut-associated denitrifying bacteria are responsible for the in vivo emission of N\textsubscript{2}O by earthworms and contribute to the N\textsubscript{2}O that is emitted from certain terrestrial ecosystems.

Biological production of the greenhouse gas nitrous oxide (N\textsubscript{2}O) is primarily mediated by microorganisms (8, 16). Soils account for 60 to 80% of the global emission of N\textsubscript{2}O (4, 5, 8–10, 21). Although abiotic processes can contribute, microbial processes are primarily responsible for the formation of N\textsubscript{2}O in soils (8, 9). The net emission of N\textsubscript{2}O at the soil surface depends on (i) production of N\textsubscript{2}O by soil microorganisms, (ii) consumption of N\textsubscript{2}O by soil denitrifying bacteria, and (iii) physical transport of N\textsubscript{2}O through the soil column. Denitrification and nitrification are the main microbial processes involved in the emission of N\textsubscript{2}O by soils (5, 8–10, 16). However, alternative microbial N\textsubscript{2}O-producing processes, such as dissimilatory reduction of nitrate or nitrite to ammonium and assimilatory reduction of nitrate for biomass synthesis, might also contribute to N\textsubscript{2}O emission (3, 19, 20, 29, 30).

It was recently demonstrated that earthworms from forest soil emit N\textsubscript{2}O under in vivo conditions (18), which suggested that earthworms are a mobile N\textsubscript{2}O-producing microsite in forest soils. The general occurrence and significance of N\textsubscript{2}O-emitting earthworms in terrestrial ecosystems, as well as the process(es) responsible for the production of N\textsubscript{2}O by earthworms, have not been determined. The two main objectives of the present study were (i) to evaluate the in vivo emission of N\textsubscript{2}O by earthworms from two contrasting, earthworm-containing soils (namely, garden and forest soils) and (ii) to determine if a gut-associated microbial process is involved in the in vivo emission of N\textsubscript{2}O by earthworms.

MATERIALS AND METHODS

Field sites and collection of earthworms. Earthworms (Aporrectodea caliginosa Sawynok, Octolasion lacteum Oeser, and Lumbricus rubellus Hoffmeister) were collected in the summer of 1997 from tilled soils (sandy loam soils) in two gardens (Heinersreuth and Weidenberg) in the vicinity of Bayreuth, Germany; properties of these soils are outlined in Table 1. The average soil dry weights of the garden soils were 78.2% ± 2.4% (Heinersreuth) and 76.2% ± 6.2% (Weidenberg). L. rubellus Hoffmeister earthworms were collected in the summer of 1996 from beech forest soils at Geisberger Forst in Germany; this site has been described previously (22). The earthworms were transported and stored in the dark in aseptic beakers containing soil or soil and litter at 10 or 15°C (depending on the in situ soil temperature) until they were used. Lumbricus terrestris L. was obtained from a local store and was stored at 4°C (the temperature used during commercial storage). The earthworms were stored for a maximum of 2 weeks before they were used and were identified by using standard protocols (28).

In situ emission of N\textsubscript{2}O. To evaluate N\textsubscript{2}O emission at the soil surface, the concentrations of N\textsubscript{2}O inside gas-tight static chambers were determined over a period of several hours. Stainless steel rings were driven about 3 cm into the ground. Plexiglas chamber tops (height, 6.5 cm; diameter, 17 cm) were placed inside the rings and sealed with large rubber seals. Gas samples were withdrawn through a rubber-stoppered port with syringes at various times after closure and were injected into evacuated, rubber stopper-sealed vials.

N\textsubscript{2}O emission by earthworms. In vivo emission of N\textsubscript{2}O by earthworms was evaluated by using aerobic microcosms that did not contain soil. Each microcosm consisted of an aseptic 38-ml serum vial that contained one living earthworm. The vials were injected into evacuated, rubber stopper-sealed vials.

normally until the end of the experiment. Gas samples were withdrawn with sterile syringes and were analyzed by gas chromatography over a period of approximately 8 h. The N$_2$O emission rate of an individual earthworm was determined during the initial period of emission.

Soil columns and soil microcosms. Each soil column consisted of a Plexiglas cylinder (height, 20 cm; diameter, 17 cm) that had a ceramic plate at the bottom and contained 2.8 kg (fresh weight) of garden soil. To assess the emission of N$_2$O from soil columns, columns were closed with Plexiglas covers (height, 5.6 cm; diameter, 17 cm) and gas-tight rubber seals for 26 h. Each soil microcosm was constructed by placing 30 g (fresh weight) of soil into a 150-ml infusion flask, which was then sealed with a rubber stopper and a metal screw cap. Earthworms were added at a density of one worm per microcosm or eight worms (four of each species) per soil column. The soil columns and microcosms were incubated at 15°C; the gas phase was air. Gas samples were withdrawn with syringes at different times after closure.

Preincubation of earthworms in soil supplemented with antibiotics. To evaluate the effect of antibiotics on in vivo emission of N$_2$O, four earthworms (L. rubellus) that were obtained from forest soil were preincubated for 3 days at 10°C in 80 g of forest soil supplemented with streptomycin and tetracycline (each at a concentration of 10 mg g$^{-1}$ dry weight) of soil$^{-1}$.

Preparation of gut sections. Freshly collected earthworms were narcotized with 100% CO$_2$ prior to dissection. Earthworm gut sections (posterior to the gizzard) were dissected out at a lab bench under air. The dissected gut sections and the remaining worm material were washed with sterile water to remove gut debris and then placed into 38-ml serum vials. The vials were sealed, incubated in the dark at 20°C, and analyzed for N$_2$O.

Preparation of microcosms with fresh casts from N$_2$O-emitting earthworms. Washed earthworms were moistened with 0.4 ml of 2 mM potassium nitrate and were incubated in microcosms under air as described above. The earthworms were removed from the microcosms after they produced casts. The microcosms containing the fresh casts were then supplemented with 0.4 ml of 2 mM potassium nitrate, rescaled, and analyzed for N$_2$O under either oxic (air) or anoxic (100% argon) conditions.

Analytical procedures. N$_2$O was analyzed with a Hewlett-Packard model 5890 series II gas chromatograph equipped with a Porapak Q column and an electron capture detector (18). Acetylene was generated from calcium carbide (CaC$_2$) and water in a gas formation flask immediately before it was used. All chemicals and gases were of the highest purity available. Unless otherwise indicated, the data are means based on four replicates.

RESULTS

In situ emission of N$_2$O at field sites. The field sites emitted N$_2$O under in situ conditions during the summer months when earthworms were collected. The rates of in situ emission of N$_2$O at the garden sites ranged from 71 to 714 nmol of N$_2$O h$^{-1}$ m$^{-2}$ (2 to 20 µg of N$_2$O N h$^{-1}$ m$^{-2}$). The rates of in situ emission of N$_2$O at the beech forest site ranged from 7 to 54 nmol of N$_2$O h$^{-1}$ m$^{-2}$ (0.2 to 1.5 µg of N$_2$O N h$^{-1}$ m$^{-2}$). These in situ emission rates were approximately the same as those of similar terrestrial ecosystems (4).

In vivo emission of N$_2$O by earthworms from garden soils and other sources. A. caliginosa, O. lacteum, and L. rubellus obtained from garden soils emitted N$_2$O under in vivo conditions (Table 2), and emission was relatively linear over a 3- to 6-h period (data not shown). The mean N$_2$O emission rates ranged from 0.14 to 0.87 nmol h$^{-1}$ g$^{-1}$ (fresh weight)$^{-1}$ (Table 2). L. rubellus obtained from beech forest soils also emitted N$_2$O under in vivo conditions (Table 2), which confirmed previous observations (18). Some individual earthworms did not emit N$_2$O, and the rates of emission of N$_2$O by earthworms were highly variable (Table 2). The emission of N$_2$O by commercially obtained L. terrestris worms was negligible; however, such worms emitted low amounts of N$_2$O when they were preincubated in garden soils (Table 2).

Although the vegetation of the garden soils and the vegetation of the forest soils were different, the rates of N$_2$O emission by the earthworms obtained from these soils were relatively similar. Thus, the theoretical quality of the soil organic carbon (decomposed beech litter in the forest soils and decomposed crops in tilled soils) did not appear to significantly affect the capacity of earthworms to emit N$_2$O. Other soil characteristics may more directly influence N turnover processes in earthworms. When the two garden sites were compared, the highest mean in vivo N$_2$O emission rates were obtained with earthworms collected from the Heinersreuth site, which contained the highest amount of soil nitrate and had the highest soil C/N ratio (Tables 1 and 2).

Emission of N$_2$O by garden soil columns and microcosms. The emission of N$_2$O by earthworm-supplemented garden soil columns was significantly greater than the emission of N$_2$O by garden soil columns lacking earthworms (Fig. 1). The emission of N$_2$O by soil columns containing or lacking earthworms was relatively linear for extended periods of time (Fig. 1). The N$_2$O emission rates were 1.4 ± 0.2 pmol h$^{-1}$ g$^{-1}$ (dry weight) of soil$^{-1}$ for columns containing both garden soil and worms and 0.3 ± 0.1 pmol h$^{-1}$ g$^{-1}$ (dry weight) of soil$^{-1}$ for columns containing garden soil alone. With garden soil microcosms, N$_2$O emission was also relatively linear (data not shown), and the emission rates were 7.6 ± 4.8 pmol h$^{-1}$ g$^{-1}$ (dry weight) of soil$^{-1}$ for microcosms containing both garden soil and worms and 0.3 ± 0.4 pmol h$^{-1}$ g$^{-1}$ (dry weight) of soil$^{-1}$ for microcosms containing garden soil alone. The calculated mean N$_2$O emission rates for the earthworms in soil columns (0.40 nmol h$^{-1}$ g$^{-1}$ [fresh weight]$^{-1}$) and microcosms (0.17 nmol h$^{-1}$ g$^{-1}$ [fresh weight]$^{-1}$)

$^b$ Earthworms were incubated in fresh garden soil for 2.5 days prior to analysis.
were similar to the in vivo emission rates obtained with individual worms (Table 2).

**Effect of mineral salts on in vivo emission of N\textsubscript{2}O.** In vivo emission of N\textsubscript{2}O was greatly stimulated when earthworms were moistened with small amounts of potassium nitrate or potassium nitrite (Fig. 2). Such stimulation was not observed with potassium chloride, ammonium chloride, or sodium sulfate (Fig. 3). Nitrate also rapidly stimulated the emission of N\textsubscript{2}O after earthworms were preincubated for 12 h in the absence of soil (Fig. 3; data not shown). The N\textsubscript{2}O emission rates increased with increasing nitrate concentrations from 0.025 to 2 mM, and the N\textsubscript{2}O emission rates were similar with 2 and 10 mM nitrate (data not shown). In all cases, the N\textsubscript{2}O emission rates obtained with nitrite were substantially greater than the N\textsubscript{2}O emission rates obtained with nitrate, and ammonium did not stimulate emission of N\textsubscript{2}O (Table 3).

**Effect of antibiotics on in vivo emission of N\textsubscript{2}O.** The in vivo emission of N\textsubscript{2}O by L. rubellus obtained from forest soil (1.95 ± 0.59 nmol h\textsuperscript{-1} g [fresh weight]\textsuperscript{-1}) decreased by approximately 80% (to 0.42 ± 0.06 nmol h\textsuperscript{-1} g [fresh weight]\textsuperscript{-1}) when earthworms were preincubated for 3 days in soil containing streptomycin and tetracycline. These results indicate that bacterial processes were involved in the production of N\textsubscript{2}O. The earthworms had a normal appearance and behaved normally after 3 days of preincubation in the antibiotic-containing soil, which indicated that the general health of the earthworms was not affected by this treatment.

**Anatomical site of N\textsubscript{2}O production.** Under oxic conditions, the capacity of nitrate-supplemented earthworm gut sections to produce N\textsubscript{2}O was substantially greater than the capacity of dissected worms lacking gut sections to produce N\textsubscript{2}O (Fig. 4), which indicated that the N\textsubscript{2}O that was produced under in vivo conditions originated in the gut rather than on the surface of the earthworm. On a fresh weight basis, the initial capacity of gut sections to produce N\textsubscript{2}O in response to supplemental nitrate was substantially greater than the capacity of living earthworms to produce N\textsubscript{2}O under the same conditions (Fig. 4).

**Effect of O\textsubscript{2} on emission of N\textsubscript{2}O by casts.** Fresh casts from N\textsubscript{2}O-emitting earthworms produced negligible amounts of N\textsubscript{2}O under oxic conditions (i.e., in the presence of air) (Fig. 5). However, under anoxic conditions, such casts rapidly produced N\textsubscript{2}O (Fig. 5). These results indicated that the microbial process responsible for the formation of N\textsubscript{2}O in the earthworm gut was sensitive to O\textsubscript{2}.

**Effect of acetylene on in vivo emission of N\textsubscript{2}O.** Collectively, the findings described above indicated that nitrate-reducing

bacteria in the gut were primarily responsible for emission of N$_2$O by earthworms. Acetylene is an inhibitor of nitrous oxide reductase and increases the production of N$_2$O by denitrifiers by blocking the last reductive step in denitrification (37). In contrast, acetylene inhibits, rather than enhances, the production of N$_2$O during dissimilatory reduction of nitrite to ammonium (20).

Acetylene increased the mean N$_2$O emission rates of earthworms that were moistened with potassium nitrate (Table 4). The increase was statistically significant for garden soil earthworms and commercially obtained, garden soil-fed _L. terrestris_. In contrast, acetylene had little or no effect on the mean N$_2$O emission rates of earthworms that were moistened with potassium nitrate (data not shown).

**DISCUSSION**

Garden and forest soils that emitted N$_2$O under in situ conditions contained earthworms that emitted N$_2$O under in vivo conditions. To estimate the contribution of earthworms to the in situ emission of N$_2$O at the garden sites, we assumed that (i) the zone of earthworm activity in the soil was 20 cm deep, (ii) the in situ earthworm population density was 100 worms per m$^2$ (an average population density for soils of central and northern Europe [27]), and (iii) the density of the garden soils was 1,200 kg (fresh weight) m$^{-2}$ (this value was the mean of values from 10 analyses). When these assumptions were used, the mean N$_2$O emission rates of garden soil columns with and without earthworms were approximately 2 and 1.3 µg of N$_2$O N h$^{-1}$ m$^{-2}$, respectively. Thus, based on these calculations, the contribution of earthworms to the total N$_2$O emitted from garden soils under field conditions was approximately 33%. Similar values were obtained when the data from soil microcosms were extrapolated to in situ earthworm population densities. Our estimates are higher than the values calculated previously for forest soils (18) and indicate that earthworms can contribute to N$_2$O emission in certain tilled soils. Since agricultural soils can have earthworm population densities as high as 400 worms per m$^2$ (11), the contribution might be even higher under certain conditions. The nitrate- and nitrite-dependent stimulation of in vivo production of N$_2$O which has been observed suggests that fertilization of soil might trigger a short-term increase in the in situ emission of N$_2$O by earthworms. Soil parameters (e.g., water content and C/N ratio) and processes (e.g., competing processes in the turnover of soil nitrogen) might also affect the in situ emission of N$_2$O by earthworms.

N$_2$O can be produced during nitrification, denitrification, and dissimilatory and assimilatory reduction of nitrate (5, 9). The enhancement of in vivo emission of N$_2$O by nitrate but not by ammonium which was observed indicated that nitrate-reducing processes, rather than nitrification, were primarily responsible for the emission of N$_2$O by the earthworms examined in this study. Since acetylene did not inhibit emission of N$_2$O by nitrite-treated earthworms, it seems unlikely that production of N$_2$O was coupled to dissimilatory reduction of nitrite to ammonium (20).

N$_2$O is an intermediate in the reduction of nitrate to N$_2$ by respiratory denitrifying bacteria (34), and N$_2$O is often a product of denitrification in soils (6, 14, 32). The acetylene-dependent increase in the emission of N$_2$O from garden and forest soil earthworms implied that denitrifying bacteria are involved in the emission of N$_2$O by earthworms. Certain denitrifying bacteria produce various amounts of N$_2$O in addition to N$_2$ or produce N$_2$O as an intermediate prior to production of N$_2$ (2, 34). Since the rate constants for the sequential steps in the reduction of nitrate to N$_2$ are probably not equivalent, the relative amounts of N$_2$O and N$_2$ may depend on whether nitrate or nitrite is utilized during denitrification (2). Thus, differences in the flow of reductant might account for the high N$_2$O emission rates observed with nitrite (Fig. 2 and Table 3). In a number of denitrifying bacteria, nitrous oxide reductase is absent (31). In these bacteria, N$_2$O is the end product of denitrification, and acetylene probably has little effect on N$_2$O production. The effect of acetylene on N$_2$O emission therefore probably depends on the composition of the resident N$_2$O-producing gut microflora. The apparent nitrate- and nitrite-dependent stimulation of N$_2$O emission may have involved nonrespiratory denitrification. In general, nonrespiratory denitrification (i) does not couple the reduction of nitrogen oxides to electron transport phosphorylation, (ii) does not yield N$_2$, (iii) is facilitated by a number of bacteria, including proteobacteria, and (iv) can yield large amounts of N$_2$O via the reduction of nitrate or nitrite (1, 19, 35).

Based on the results obtained with dissected earthworms,
the N\textsubscript{2}O that was emitted by earthworms originated from gut-associated microorganisms. Since nitrate and nitrite significantly stimulated in vivo emission of N\textsubscript{2}O, it seems likely that supplemental nitrate or nitrite was transported into the gut, where denitrifying bacteria (18) and production of N\textsubscript{2}O were localized. Uptake of water or dissolved salts by earthworms usually does not involve oral ingestion of fluids (26). Thus, it is likely that nitrate and nitrite were translocated through the body wall and into the gut via either passive diffusion or active transport (23, 26). Differences in the efficiencies by which nitrate and nitrite were transported into the gut might be partially responsible for the differences observed in the N\textsubscript{2}O emission rates of earthworms treated with nitrate and nitrite. The nitrate- and nitrite-dependent stimulation of N\textsubscript{2}O emission by earthworms and gut sections was rapid and occurred without an appreciable delay, indicating that (i) the source of reducible used for the production of N\textsubscript{2}O was not limiting and (ii) the N\textsubscript{2}O-producing microflora of the gut was poised to respond quickly to nitrate and nitrite.

In contrast to living earthworms and gut sections that produced N\textsubscript{2}O under anoxic conditions (i.e., in the presence of air), fresh casts from N\textsubscript{2}O-emitting earthworms produced N\textsubscript{2}O only under anoxic conditions. These results indicate that the N\textsubscript{2}O production process in the earthworm gut occurs optimally under anoxic conditions and, furthermore, suggests that the interior of the earthworm gut provides an anoxic (or partially anoxic) habitat for microbial production of N\textsubscript{2}O. The microflora of the earthworm gut is enriched with bacteria capable of anaerobic growth and activity (17), and several strictly anaerobic bacteria, as well as facultatively anaerobic bacteria, have been obtained from the earthworm gut and earthworm casts and characterized (7, 15, 18, 24). Denitrifiers have been observed in earthworm casts collected from agricultural soils (12, 13, 25, 33) and have been enumerated from the gut material of earthworms collected from forest soil (18). Commercially obtained earthworms emitted N\textsubscript{2}O only when they were preincubated in fresh soil (Table 2), indicating that (i) N\textsubscript{2}O-producing microbes in the soil were ingested or (ii) ingested soil provided essential nutrients to the N\textsubscript{2}O-producing microflora of the gut. Characterization of the N\textsubscript{2}O-producing bacteria of the earthworm gut is currently under way.

The activities of gastrointestinal microfloras are linked to the greenhouse gas budget. For example, it has been estimated that the gut microfloras of livestock and termites are responsible for approximately 30% of the global methane budget (36) and that the gut microflora of cattle is responsible for approximately 2% of the global N\textsubscript{2}O budget (i.e., 0.5 Tg year\textsuperscript{-1}) (21). Our findings indicate that the gastrointestinal microflora of the earthworm contributes to the global N\textsubscript{2}O budget. Determining the extent of this contribution will require extensive evaluation of the diverse terrestrial ecosystems in which earthworms are endemic.
