Received 20 June 2002/Accepted 27 September 2002

The production of an ant-deterrent factor(s) (ADF) by Xenorhabdus nematophila and Photorhabdus luminescens, the symbiotic bacteria of the nematodes Steinernema carpocapsae and Heterorhabditis bacteriophora, respectively, was examined. In addition to an in vivo assay in which bacteria were tested for their ability to produce ADF within insect cadavers (M.E. Baur, H. K. Kaya, and D. R. Strong, Biol. Control 12:231-236, 1998), an in vitro microtiter dish assay was developed to monitor ADF activity produced by bacteria grown in cultures. Using these methods, we show that ADF activity is present in the supernatants of bacterial cultures, is filterable, heat stable, and acid sensitive, and passes through a 10-kDa-pore-size membrane. Thus, ADF appears to be comprised of a small, extracellular, and possibly nonproteinaceous compound(s). The amount of ADF repellency detected depends on the ant species being tested, the sucrose concentration (in vitro assays), and the strain, form, and age of the ADF-producing bacteria. These findings demonstrate that the symbiotic bacteria of some species of entomopathogenic nematodes produce a compound(s) that deters scavengers such as ants and thus could protect nematodes from being eaten during reproduction within insect cadavers.
Habitats throughout much of California (12, 25), was tested for its response to
and laboratory experiments. Control larvae injected with Ringer
solution (17). Using a hemocytometer, a bacterial count was made for each
larva (Rainbow Mealworms, Inc., Compton, Calif.) with bacteria
isolated by H. Goodrich-Blair from surface-sterilized infective-stage S. car-
pocapsae. All strain nematodes by homogenization (27).

### MATERIALS AND METHODS

**Strains, propagation, and storage conditions.** Nematode strains used were
*Steinernema carpocapsae* (Weiser) All and *Heterorhabditis bacteriophora* Poinar
NC1. All nematodes were reared in wax moth larvae as previously described (17) and
stored in water at 15°C for no more than 5 weeks before they were used. S. carpocapsae nematodes carrying HGB007 bacteria were generated by cultivating sterile nematode eggs on lawns of HGB007 and harvesting the progeny IJs in water traps as previously described (11, 23, 24). Subsequent rearing was
conducted in wax moth larvae as previously described (17). *Xenorhabdus and Phy-
rorhabdus* bacterial strains used in this study are listed in Table 1. The bacteria
were streaked on NBTA (10) as needed to detect possible phenotypic variation
before using them in experiments. 1°-form bacteria were used in all experiments
except where specified. Bacteria taken from –70°C stocks were either trans-
ferred directly into liquid culture or were first transferred to NBTA medium,
grown for 48 h, and then transferred to liquid culture. For liquid culture, bacteria
were grown at 28 to 30°C aerated in nutrient broth (NB) (Difco, Detroit, Mich.)
or Luria-Bertani broth (LB) (18) for the lengths of time indicated for each experiment.

**Ant test sites.** Three field sites—the University of California, Davis (UC-Davis)
campus (Yolo County), a marina in Berkeley, California (Alameda County), and
the University of Wisconsin, Madison (UW-Madison) campus (Dane County)—were
chosen for experiments in the natural habitats of the ants. The Argentine ant, *L. humile*, which is common in disturbed areas such as urban and agricultural
habitats throughout much of California (12, 25), was tested for its response to
bacterial secondary metabolites at the first two locations. *L. alienus* and *F. subsericea*, identified by Philip Ward (UC-Davis), were studied at the Wisconsin
site.

To establish laboratory ant colonies, *L. humile* workers, queens, and broods
were collected in the field by digging up the nests with soil and leaf litter in Davis,
California. The ants were allowed to form nests as described by Baker et al. (1). Briefly, plastic petri dishes (100 by 15 mm) were partially filled with plaster of Paris which, once hardened, was kept moist by a wink submerged in water. Ants
established nests in the dishes after the infested material (soil or litter) was placed
in a bucket, and water was added. As the water level rose, the ants took refuge in
the petri dish, which was covered with red cellophane to create a dark
environment. Eleven colonies, ranging from about 2,000 to 5,000 individuals/
colony, were established.

**In vivo ADF activity assays (California test sites only).** Bacterial-infected insects
used in ADF assays were obtained by injecting last-instar *Galleria mellonella* (L.) larvae (Rainbow Mealworms, Inc., Compton, Calif.) with bacteria
that had been grown on NBTA for 48 h and then suspended in sterile Ringer’s
d solution (17). Using a hemocytometer, a bacterial count was made for each
culture. On the basis of this count, each culture was diluted so that there were
approximately 100 bacterial cells/μL. Ten microliters of the bacterial suspension
was injected into the second proleg of a chilled larva (held at 4° C for 10 min) with
a 27-gauge needle on a 2-ml syringe. Sterile Ringer’s solution was used as a
control. The injected larvae were placed in petri dishes and incubated at room
temperature for 4 days. The 4-day-old bacterium-killed larvae were used for field
and laboratory experiments. Control larvae injected with Ringer’s solution were
frozen for at least 2 h and used as freeze-killed controls.

**In vitro assays for ADF activity.** Due to different response levels of California
and Wisconsin ants to ADF and sucrose attractant, different protocols were
developed for use at each location. However, unless noted otherwise, minor
differences in protocols (e.g., bacterial growth medium, test suspension volume,
monitoring method) did not cause qualitative differences in the results obtained
for the California and Wisconsin field sites. Regardless of the protocol, 96-well
polyvinyl chloride microtiter plates (from Becton Dickinson [Oxnard, Calif.] or
Corning Laboratory Science Company [Corning, N.Y.]) were used to hold the
test suspensions. In all experiments, the arrangement of bacterial suspension
in the wells of each plate was completely randomized, and samples were compared
with water controls to determine when the difference between the pre- and
postexperimental amounts was due to evaporation. Each well contained 0.2 to
0.21 ml of test suspension, and the substrate remaining after testing was mea-
sured by volume or weight. We observed that *L. humile* ants congregated on the
rows or columns near the edges of the plates and did not proceed inward until the
sucrose suspension in the well near an edge was consumed. To avoid this “edge
effect,” only the wells along one side were used for all experiments with *L. humile*
ant species, and one side of the plate was coated with a sucrose solution to attract ants
to the plates. The Wisconsin ant species studied, *L. alienus* and *F. subsericea*, did not show a preference for edge wells. For these ants, flexible polyvinyl chloride
microtiter plates were cut to size such that all wells in the block were used (e.g.,
3 X 8 for an experiment with eight treatments). Each block was placed in a
standard 10-cm-diameter plastic petri dish in which four holes were made at roughly equal distances in the side walls using a heated no. 1 cork borer to give ants access to the wells and placed near a different ant trail or nest.

California experiments were performed all year at temperatures ranging from
15 to 30°C for field experiments compared to 23 ± 2°C for laboratory experi-
ments. Wisconsin experiments were limited to field trials between July and
September, with temperatures ranging from 8 to 34°C.

In California, after placement, ant counts were conducted at the same intervals
as for the field experiments, and the experiment was terminated in less than 60
min if any one suspension was consumed prior to this time. Two wells for each
treatment were used in a plate (a replicate). Except where noted otherwise, eight
replicates (plates) were included in each experiment. In Wisconsin, there were
three replicate wells for each treatment in each well block, and there was a
minimum of two blocks per experiment. *L. alienus* and *F. subsericea* were allowed
to feed on the substrates for a minimum of 6 h (observation by ants was not
monitored during this time).

**Ant behavior.** *L. humile* was the only ant species observed in and around the
field sites in Davis, California. Generally, it took 5 to 10 min and 1 to 2 min for
worker ants to locate the insect cadavers or bacterial suspensions in the field and
laboratory experiments, respectively. There were more ants on the cadavers
during the first 1 to 2 h after placement than 2 h after placement in laboratory
trials, but ants fed on freeze-killed insects at the same intensity during the
duration of the field trials. Approximately 100 to 150 ants were required to
completely consume the sucrose control solution in one well. A well can host ca.
45 ants at one time during the feeding period. An individual ant spent 1 to 2 min
at a well before moving to another well containing fresh suspension for another
feeding bout.

Similar observations were made at the Wisconsin site. Test suspensions
were located by worker ants within 10 min and visited at high intensity within 30 min.

* Form variants were identified by observing colony color and zone of clearing on NBTA medium (10).

* ATCC, American Type Culture Collection (Rockville, Md.).

* In the lab of H. Goodrich-Blair, HGB030 was isolated from an aged culture of HGB007 and HGB159 was isolated from an aged culture of HGB008.

* Isolated by H. Goodrich-Blair from surface-sterilized infective-stage *S. carpocapsae*. All strain nematodes by homogenization (27).

ADF activity was evaluated by consumption only. Time for complete consumption of the sucrose control treatments depended on ant size, colony size, weather conditions, and frequency of testing at the specific site (i.e., starvation level of the ants) but usually varied between 2 and 6 h. Ants sampled all wells but concentrated their efforts on consuming control wells or those with least ADF activity. Once these wells were completely emptied, the process continued until the ants encountered the wells where the ADF activity completely prohibited consumption.

Biochemical characterization of ADF. For experiments to test the effects of filtration on ADF activities from isolates HGB007 (cultured for 108 h), HGB008 (cultured for 132 h), and HGB325 (cultured for 132 h), cell-free supernatants were prepared by centrifuging bacterial suspensions at 2,000 × g for 20 min and passing each supernatant through a 0.45-μm-pore-size Millipore filter (Millipore, Bedford, Mass.). Nonfiltered cultures served as controls.

Heated samples for in vitro assays were obtained by autoclaving (121°C for 20 min) cell-free supernatants of HGB007, HGB008, and HGB325 isolates. Nonautoclaved cultures and autoclaved NB served as controls. For in vivo assays, autoclaved bacterium-killed insects served as the heated treatment, whereas nonautoclaved cadavers served as the nonheated treatment. Freeze-killed wax moth larvae that had been autoclaved or had not been autoclaved served as controls.

For experiments testing the effect of pH on ADF activity, a cell-free supernatant from a culture of the HGB007 isolate grown for 48 h (pH 8.4) was divided, put into six separate tubes, and adjusted to pH 2, 4, 6, 8, 10, or 12 with either 0.1 M HCl or 0.1 M NaOH, followed by the addition of sucrose to 25%. Control samples of 25% sucrose adjusted to the same range of pH were included in the experiment, which was conducted twice according to the Wisconsin trial conditions.

For molecular weight analyses, cell-free supernatants from HGB007 cultures that had been grown for 48 h were separated by size on a Centricon 10-kDa-cutoff filter (Millipore) into eluate (<10-kDa) and retentate (>10-kDa) fractions. Each fraction was normalized by the addition of water to the proportional weight/volume of the input solute. A reconstituted sample was prepared by mixing eluate with retentate in the same proportions as in the original sample. Sucrose and water samples served as a control. The experiment was performed twice, each time with a different supernatant preparation, according to the in vitro Wisconsin test site conditions.

Statistical analysis. The number of worker ants visiting the insect cadavers or suspension treatments, the amount of suspension removed from wells, and the number of intact cadavers were transformed into proportional data. The proportion of ants visiting one treatment was calculated as follows. The number of ants visiting that treatment (total of two wells) at each 10-min interval was totaled and divided by the total number of ants visiting all the treatments in a given plate. The proportion of suspension removed in a treatment was obtained by dividing the suspension removed in one treatment (total of two wells) by the original volume of suspension present in the treatment at the start of the assay. Proportional data were arcsine-square root transformed before conducting a two-way analysis of variance and then Duncan’s new multiple-range test (21).

Untransformed data, such as percentage of suspension removed, are reported, and mean values ± standard errors are provided.

RESULTS

Effect of sucrose concentration on ADF activity. Sucrose was used to attract ants in in vitro assays, and its concentration was tested for its impact on L. humile ant visitation behavior and feeding during monitoring of bacterial deterrence. The bacterium used for this purpose was HGB007, an X. nematophila strain that had exhibited the ability to deter ants at the Wisconsin field site. It should be noted that Escherichia coli cultures are readily visited and consumed by ants (Table 2) and that ADF activity is not a general property of bacterial cultures. Sucrose was added to various concentrations to culture medium with and without HGB007 and tested against L. humile ants.

Ant visitation was measured in two independent trials of 10 treatments each (5 treatments for NB and 5 treatments for HGB007) (data not shown). The proportion of the ant population visiting wells containing sucrose concentrations of ≥10% was significantly higher than those visiting wells with no sucrose or with a sucrose concentration of 5% (trial 1, F = 117.83, df = 9, 140, P < 0.0001; trial 2, F = 51.76, df = 9, 140, P < 0.0001). In each of these trials, the proportion of ants visiting NB and HGB007 wells with no sucrose was low (< 0.02).

The extent to which ants consumed test solutions was proportional to the amount of sucrose that was present (Fig. 1). Ants do not consume solutions containing no added sucrose and visit such solutions less frequently. Interestingly, the amount of 5% sucrose solution consumed was decreased if a bacterial suspension was added to the sucrose solution (Fig. 1); however, this effect was masked at sucrose concentrations of ≥10%. We developed an assay using the 5% sucrose solution as a base, and we defined ADF activity as the ability of added bacterial suspensions or culture supernatants to deter normal levels of either ant visitation or solution consumption.

These data are in contrast to the feeding behavior of L. alienus and F. subsericea ants. These ants appeared to be more sensitive to ADF activity and did not consume HGB007 cultures with 25% sucrose (Table 3). All subsequent experiments with L. humile were therefore performed with 5% sucrose concentrations, whereas for experiments with L. alienus or F. subsericea, 25% sucrose concentrations were used.

Time course of ADF production in vitro. At the Wisconsin test site, it was found that cultures of HGB007 (X. nematophila) grown for 48 h had more ADF activity, measured by a reduction in ant consumption of test solutions, than cultures grown for 24 h (data not shown). In fact, under Wisconsin in vitro assay conditions, the HGB007 cultures grown for 48 h usually had attained a maximal level of deterrence activity (i.e., very little suspension removed from the wells). Therefore, this growth time was used for all test cultures at the Wisconsin site.

* See Materials and Methods for detailed explanation of test conditions.

* See Table 1 for details on the strains. E. coli, E. coli (Migula). Control, freeze-killed insects used for in vivo experiments.

* For in vitro assays, values are the proportion of volume (in microliters) removed from wells. For in vivo studies, values are the mean proportion of ants visiting the E. coli control versus the bacterial treatments (F = 54.33, df = 2, 32; P < 0.05).

* Significantly more suspension remained in the wells of 1° or 2°-form bacterial treatments than that for the E. coli control treatment (F = 4697.98, df = 2, 32; P < 0.05).

* There was a significant difference between the treatments of 1° and 2°-form bacteria or freeze-killed control (F = 67.5, df = 2, 67; P < 0.0001).

* NA; not applicable.
In contrast, maximal ADF activity was not observed by 48 h of bacterial growth at the California sites. Therefore, the timing of appearance of ADF activity at these sites was assessed. Samples from HGB007 (X. nematophila) and HGB008 (P. luminescens) cultures were taken at various times over a 132- and 144-h time period, respectively, and tested for deterrence of ant visitation (Fig. 2). There were significant differences in the mean proportions of ants visiting HGB008 with the different bacterial growth times ($F = 89.94$, df = 12, 436; $P < 0.001$). Ant visitation to samples taken after 84 h of bacterial growth decreased (i.e., ADF activity increased) and was lowest ($P > 0.05$) for samples taken at 132 h of bacterial growth.

The length of time of bacterial growth also affected the ants’ response to HGB007 ($F = 119.46$, df = 11, 216; $P < 0.0001$) (Fig. 2). There was a sharp decrease in visitation to HGB007 samples taken from cultures grown for 0 versus 12 h and a steady decrease in visitation of ants to samples taken after 12 h of growth, with the lowest visitation to samples from cultures grown for 108 h. For all subsequent California in vitro ADF activity experiments, X. nematophila strains were grown for 108 h, and P. luminescens strains were grown for 132 h.

**Production of ADF activity in vivo.** We tested the response of *L. humile* to insects killed by different nematode-bacterium pairs and found a significant difference in ant response depending on the bacterial strain harbored by the nematode ($F = 412.38$, df = 3, 203; $P < 0.0001$) (Fig. 3A). Ants approached and touched the insects killed by *S. carpocapsae* harboring HGB007 and *H. bacteriophora* harboring *P. luminescens* HGB326 and then left the cadavers. In contrast, the proportion of ants that fed on the insects killed by *S. carpocapsae* carrying HGB001 was significantly higher.

We then assessed ADF activity in larvae that had been killed by direct injection (i.e., without any nematodes) of strains of *Xenorhabdus* (HGB007) and *Photorhabdus* (HGB008 and HGB325) by monitoring *L. humile* ant visitation at the California test sites. As expected, the ants responded differently to bacterium-killed versus freeze-killed insect hosts in the field (Fig. 3B) and lab (data not shown). In field experiments, significantly more ants fed on the freeze-killed insects than on any of the bacterium-killed insects ($F = 36.7$, df = 3, 101; $P < 0.001$) (Fig. 3B). Ninety-six percent of the freeze-killed insects were no longer intact, and the other 4% were missing after the 24-h experiment. In contrast, only 6% of the bacterium-killed insects had their integument punctured, and the remaining cadavers were intact. Similar results were obtained when larvae...
killed by various bacterial strains when grown in laboratory growth medium. Xenorhabdus (HGB001 and HGB007) and Photorhabdus (HGB008, HGB325, HGB326, and HGB327) strains were grown in NB and tested for visitation by L. humile in the California field sites (Fig. 3C). There were significant differences in the different treatments ($F = 290.73, \text{df} = 6, 480; P < 0.0001$), with the highest proportion of ants feeding on control wells (NB plus 5% sucrose), which was significantly higher than that for other treatments. All NB-cultured Xenorhabdus and Photorhabdus strains tested had some measurable ADF activity against Argentine ants, with HGB326 having the least activity and HGB007 having the most activity.

**Effect of phenotypic variation on ADF activity.** The effect of phenotypic variation on ADF activity produced by HGB007 cultures grown for 48 h was assessed in field experiments in Wisconsin (Table 3). Cultures of 2°-form X. nematophila (HGB030) did not show ADF activity; ants consumed the entire mixture. The effect of HGB008 phenotypic variation was measured at field and laboratory sites at Davis, Calif. (Table 2). Surprisingly, phenotypic variation did not affect ant response to P. luminescens grown in laboratory culture but did affect ant response to P. luminescens in insect larvae. While ants did not consume either 1°- or 2°-form P. luminescens grown in NB, they did consume the sucrose-only control treatment. In contrast, while ants did not visit or attempt to eat larvae killed by 1°-form P. luminescens (HGB008), they did visit larvae killed by 2°-form P. luminescens (HGB159). In fact, there was no significant difference in the proportion of ants visiting 2°-form P. luminescens-killed insects versus freeze-killed insects ($F = 0.14, \text{df} = 3, 127; P > 0.70$). A similar response was observed with the cadavers in the 11 laboratory ant colonies (data not shown).

**Biochemical characterization of ADF activity.** We conducted several experiments to begin characterizing the biochemical nature of ADF. First, the effect of filtration on ADF activity from supernatants of cultures of HGB007 (grown for 108 h), HGB008 (grown for 132 h), and HGB325 (grown for 132 h) was determined by monitoring L. humile visitation in laboratory and field Argentine ant colonies. It was found that ants per plate. (B) The mean proportion of field ants visiting wax moth larvae killed by injection with the bacterial strains indicated below each bar or by freezing (Control). Twenty-five replicates were used, and the experiment was repeated six times. Each replicate consisted of two cadavers from each treatment (total of eight cadavers) in a plastic petri dish and placed at four field sites in Davis, Calif., over a 2-week period. There was no significant difference ($P > 0.05$ by Duncan’s new multiple-range test) between the values with the same lowercase letter above the bars. The sample size ranged from 25 to 81 ants per plate. (C) Photorhabdus and Xenorhabdus strains were grown in NB for 132 and 108 h, respectively, and tested against field colonies of Argentine ants. Mean ($\pm$ standard error) proportion of ants visiting the supernatants of six different bacterial strains (identified below each bar) or a medium-only control (NB) is given. The experiment was conducted once, with eight replicates, in the Davis field site. There was no significant difference ($P > 0.05$ by Duncan’s new multiple-range test) between the values with the same lowercase letter above the bars. The sample size ranged from 50 to 136 ants per plate.

FIG. 3. ADF activity produced by various Photorhabdus and Xenorhabdus strains. (A) The mean proportion of field ants visiting wax moth larvae killed by *Heterorhabditis* or *Steinernema* nematodes colonized by different bacterial isolates. *S. carpocapsae* All (S.c.) and *H. bacteriophora* NC1 (H.b.) nematodes with HGB001, HGB007, and HGB326 bacteria were studied. Freeze-killed insects were used as the control. There were eight replicates with two cadavers in each treatment, and the experiment was repeated twice. Means with the same letter above the bar are not significantly different ($P > 0.05$ by Duncan’s new multiple range test). The sample size ranged from 47 to 196.
laboratory ants were deterred by the filtered and nonfiltered bacterial cultures equally (data not shown). A similar response was detected in the field, where there was no significant difference between filtered and nonfiltered bacterial treatments, with 13% of ants visiting the wells for all the nonfiltered bacterial treatments and 12% of ants visiting for all the filtered treatments ($F = 0.2$, $df = 1, 71$; $P = 0.655$). The control treatments of filtered and nonfiltered NB showed a significantly higher ($F = 318.78$, $df = 3, 71$; $P < 0.0001$) proportion of ants visiting compared to the bacterial cultures, with a mean value of ca. 38% ants for both the filtered and nonfiltered control treatments.

Cell-free supernatants of cultures of HGB007 (grown for 108 h), HGB008 (grown for 132 h), and HGB325 (grown for 132 h) were autoclaved to determine the effect of heat treatment on ADF activity as detected by consumption of solutions (Fig. 4A). There was no significant difference between autoclaved and nonautoclaved treatments ($P > 0.9$). Field experiments were consistent with lab experiments in that there was no significant difference between the amounts of suspension left in the heated and nonheated treatments ($P > 0.79$), with 0.12 ml (60%) for the nonautoclaved treatments and 0.11 ml (55%) for the autoclaved treatments (data not shown). Again, the difference among the bacterial treatments was not significant ($P > 0.05$) and a highly significant difference was observed between the bacterial and control treatments ($F = 96.51$, $df = 7, 98$; $P < 0.0001$) (data not shown).

As a further test of the heat stability of ADF, insect larvae killed by HGB007, HGB008, or HGB325 were autoclaved and compared with nonautoclaved larvae for their effect on ant visitation. *L. humile* did not respond to the autoclaved and nonautoclaved bacterium-killed insects differently (Fig. 4B).

To assess the approximate molecular size of ADF, cell-free supernatants of HGB007 cultures (grown for 48 h) were fractionated on a 10-kDa pore-size membrane and tested for ADF activity at the Wisconsin test site by measuring consumption of substrate (mean $\pm$ standard error) from wells (in ascending order) were as follows: water, $0.17 \pm 0.04$; eluate, $0.38 \pm 0.03$; supernatant, $0.45 \pm 0.04$; reconstituted eluate plus retentate, $0.47 \pm 0.03$; retentate, $0.89 \pm 0.05$; sucrose, $1 \pm 0$. There were significant differences ($F = 26.7$, $df = 6, 10$; $P < 0.0001$) among the treatments, demonstrating that ADF activity was present in the $<$10-kDa eluate and supernatant.

Cell-free supernatants of HGB007 cultures (grown for 48 h) were tested at the Wisconsin test site for the effect of pH on consumption. *L. alienus* and *F. subsericea* ants consumed sucrose controls of each pH tested (data not shown), but ADF activity in test strains was lost at low pH values. The precise pH at which activity was lost depended on the ant species. *L. alienus* ants consumed supernatants of pH 6.0 or less, while *F. subsericea* ants were still repelled by supernatants at pH 4.0 and pH 6.0 but not by supernatant at pH 2.0 (data not shown).
DISCUSSION

The results of our experiments show that the symbiotic bacteria of certain entomopathogenic nematodes produce a factor(s), ADF, which deters ants from visiting and/or feeding on otherwise attractive substrates of either sucrose or dead insect larvae. These results are consistent with the observations of Baur et al. (2), and differences in observed ADF activity between the two studies can be readily explained by differences in strains, forms, growth rate, and/or cell count.

Although _Photorhabdus_ and _Xenorhabdus_ species occupy the same pair of ecological niches (the intestines of symbiotic nematodes and the hemocoeol of insects) _Heterorhabditis-Photorhabdus_ and _Steinernema-Xenorhabdus_ entomopathogenic nematode-bacterium complexes are widely divergent and have separate origins (4, 20). In fact, there is less than 20% identity between the genomic DNA from species in the _Xenorhabdus_ and _Photorhabdus_ genera (5). Poinar (20) concluded that a similar pattern of infectivity, life cycle, and association with bacterial symbionts is the result of convergent evolution. In light of this hypothesis, it is possible that the ADF activities produced by _Xenorhabdus_ and _Photorhabdus_ are distinct compounds and that ADF production is also an example of a convergently evolved function.

There are major physiological differences between the 1° and 2° forms for both _Xenorhabdus_ and _Photorhabdus_ bacteria (3, 6, 8). For example, 1°-form variants produce more antibiotics and show differences in their ability to absorb certain dyes compared to 2°-form variants. The two variants produced different levels of ADF activity under some, but not all, test conditions. _X. nematophila_ HGB030 (2° form derived from HGB007) did not produce ADF activity when tested in vitro at the Wisconsin test site (Table 3). In contrast, _P. luminescens_ HGB159 (2° form) exhibited ADF activity under in vitro conditions, but not when injected into insects (in vivo) (Table 2). One possible explanation for these differences may be that growth of 2°-form _P. luminescens_ within insects is not optimal for production of ADF. Alternatively, the mechanisms of phenotypic variation, and, in turn, the regulation of ADF production, may be distinct between _Xenorhabdus_ and _Photorhabdus_ genera.

Under in vitro conditions, higher sucrose concentrations in the suspensions resulted in more ants feeding, indicating that sucrose masked the effects of ADF. However, experimental conditions, such as test location or ant species used, yielded differences in the level of sucrose required for masking. These differences may have been due to different sensitivities of the ant species used in each location, differences in culture medium and time, or differences in some other variable parameter of the field sites.

The length of time postinfection or bacterial culture time can greatly impact the titer of ADF. Kaya et al. (16) observed that _Pheidole megacephala_ (Fabricius) heavily scavenged insects killed by entomopathogenic nematodes that were less than 4 days postinfection of the nematode. The data indicated that the ADF titer was low, suggesting that the bacteria did not produce sufficient ADF during the early infection period. Other invertebrate scavengers such as earwigs, cockroaches, and slugs may also feed on nematode-killed insects in the early stages of nematode development and abort IJ production (16). California in vitro experiments (Fig. 2) showed that _X. nematophila_ HGB007 ADF activity against _L. humile_ was greatest when cells were grown for 108 h and _P. luminescens_ HGB008 ADF activity was greatest in samples taken after 132 h of growth, consistent with the results of in vivo experiments. An extensive time course experiment was not conducted at the Wisconsin test site since, under these conditions, bacterial cultures grown for 48 h produced sufficient ADF activity to completely deter _L. alienus_ and _F. subsericea_ ants when resuspended in 25% sucrose.

Our data revealed a number of characteristics of ADF, although it should be stressed that more than one compound could have deterrent activity. ADF from _X. nematophila_ HGB007 is present in the cell-free supernatant and can pass through a 0.45-μm-pore-size Millipore filter, indicating that ADF is extracellular. Autoclaving supernatants did not eliminate ADF activity; therefore, the compound(s) may be non-proteinaceous. Molecular size fractionation of filtered supernatants suggests that ADF from _X. nematophila_ HGB007 is a small compound of less than 10 kDa, and it was found that ADF is sensitive to acidic pH. Interestingly, these attributes are similar to those of β-exotoxin of _Bacillus thuringiensis_ Berliner, an insect feeding deterrent (19).

This work confirms and extends previous observations that the production of ADF activities by entomopathogenic bacteria plays a significant role in protecting nematode-killed insects from scavengers (2). Scavengers can be detrimental to the nematodes if the cadavers are damaged or consumed before the nematodes can complete their life cycle, and the production of ADF by symbiotic bacteria may serve to protect the cadaver and the nematodes within. Thus, ADF production can be added to the list of compounds produced by symbiont bacteria (such as antibiotics) that increase the fitness of the nematodes (7).

Scavengers, such as ants, can adversely affect the persistence of entomopathogenic nematodes being used as biological control agents. We have shown that ADF produced by the nematodes’ symbiotic bacteria can deter ants from feeding on nematode-killed insects. Future research is needed to elucidate the nature of ADF, isolate the gene(s) required for expression of ADF, and determine the range of its activity against insects and other arthropods or vertebrates. The results of such studies may lead to an enhancement of ADF activity and to ADF-fortified nematode application as a viable approach to agricultural and structural pest management.

ACKNOWLEDGMENTS

Work in H. Goodrich-Blair’s laboratory was supported in part by USDA/CREES grant CRHF-0-6055 and by National Institutes of Health R01 grant GM59776 (awarded to H.G.B. and used for K.H. support). Work in H. K. Kaya’s laboratory was supported in part by the Genetics Resources Conservation Program.

We thank Lester E. Ehler, Eric Martens, and Samantha Orchard for helpful comments on the manuscript.
