Received 28 May 2004/Accepted 15 September 2004

Lactose is the only soluble and economically feasible carbon source for the production of cellulases or heterologous proteins regulated by cellulase expression signals by \textit{Hypocrea jecorina} (anamorph, \textit{Trichoderma reesei}). We investigated the role of the major \( \beta \)-galactosidase of \textit{H. jecorina} in lactose metabolism and cellulase induction. A genomic copy of the \textit{bga1} gene was cloned, and this copy encodes a 1,023-amino-acid protein with a 20-amino-acid signal sequence. This protein has a molecular mass of 109.3 kDa, belongs to glycosyl hydrolase family 35, and is the major extracellular \( \beta \)-galactosidase during growth on lactose. Its transcript was abundant during growth on L-arabinose and L-arabinotol but was much less common when the organism was grown on lactose, D-galactose, galactitol, D-xylitol, and xylitol. \textit{bga1} strains grow more slowly and accumulate less biomass on lactose, but the cellulohydrolase I and II gene expression and the final cellulase yields were comparable to those of the parental strain. Overexpression of \textit{bga1} under the control of the pyruvate kinase promoter reduced the lag phase, increased growth on lactose, and limited transcription of cellulohydrolases. We detected an additional extracellular \( \beta \)-galactosidase activity that was not encoded by \textit{bga1} but no intracellular \( \beta \)-galactosidase activity. In conclusion, cellulase production on lactose occurs when \( \beta \)-galactosidase activity levels are low but decreases as the \( \beta \)-galactosidase activities increase. The data indicate that \textit{bga1}-encoded \( \beta \)-galactosidase activity is a critical factor for cellulase production on lactose.

The ascomycete \textit{Hypocrea jecorina} (anamorph, \textit{Trichoderma reesei}) is used industrially to produce cellulolytic and hemicellulolytic enzymes, and its strong cellulase promoters are of interest for heterologous protein production by this fungus. Cellulase and hemicellulase formation can be induced by several mono- and disaccharides, including sorbose, xylobiose, lactose, D-xylitol, and L-sorbine, most of which are too expensive for industrial fermentations. Thus, the range of technically applicable carbon sources is limited. For cellulase and hemicellulase production with cellulase promoters, lactose (1,4-O-\( \beta \)-d-galactopyranosyl-\( \beta \)-glucose) is virtually the only carbon source that can be used. However, the mechanism by which lactose triggers cellulase formation is not understood. Lactose metabolism is slow, and the cellulase yields on lactose are lower than those on cellulose (27, 28).

A key enzyme in the induction of cellulase is galactokinase, which lactose triggers cellulase formation is not understood. Lactose metabolism is slow, and the cellulase yields on lactose are lower than those on cellulose (27, 28).

A key enzyme in the induction of cellulase is galactokinase, since a galactokinase-negative mutant cannot induce cellulases during growth on lactose (30). Lactose can enter the cell after it is hydrolyzed extracellularly to D-glucose and D-galactose by a \( \beta \)-galactosidase (lactase, \( \beta \)-D-galactoside galactohydrolase; E.C 3.2.1.23), and the monosaccharides are then taken up by the respective permeases. Extracellular \( \beta \)-galactosidases are known from several fungi, including \textit{Aspergillus niger}, \textit{Aspergillus oryzae}, and \textit{Penicillium canescens} (5, 21, 26, 29). Alternatively, the lactose itself can be taken up by a specific lactose permease and hydrolyzed intracellularly. The latter mechanism has been demonstrated in the yeast \textit{Kluveromyces lactis} (6, 11), and \textit{Aspergillus nidulans} is known to contain both an intracellular \( \beta \)-galactosidase (12) and a lactose permease (L. Karaffa, B. Seiboth, and C. P. Kubicek, unpublished data). \textit{H. jecorina} has been reported to have extracellular \( \beta \)-galactosidase activity (25).

The objectives of the present work were to clone the \textit{bga1} gene encoding the extracellular \( \beta \)-galactosidase of \textit{H. jecorina} and to address the following questions. (i) Does \textit{H. jecorina} contain other \( \beta \)-galactosidases, in particular intracellular \( \beta \)-galactosidases? (ii) Is the rate of extracellular lactose hydrolysis critical for induction of cellulases by lactose? And (iii) does manipulation of \( \beta \)-galactosidase activity improve cellulase production on lactose? This information is needed to design and control industrial cellulase production with lactose as the carbon source.

Materials and Methods

Strains and culture conditions. \textit{H. jecorina} strain QM9414 (= ATCC 26921) and strain RUT C30 (= ATCC 56765) and its \textit{pyr4} mutant TU-6 (= ATCC MYA-256) (15) were maintained on malt extract agar supplemented with uridine (10 mM) as necessary. Strains were grown in 1-liter flasks on a rotary shaker (250 rpm) at 30°C in the medium described by Mandels and Andreotti (23) with the appropriate carbon source at a final concentration of 10 g/liter. For transcript analysis, strains were pregrown on glycerol (1%, wt/vol) for 20 h, mycelia were harvested by filtration and washed with tap water, equal amounts of mycelia were transferred to flasks containing the appropriate carbon source (1%, wt/vol), and cultivation was continued for 3 to 6 h. For lactose analysis, expression was analyzed without pregrowth on glycerol.

Ehcherichia coli strain NM538 (13) was used for library screening, and strains JM109 (Promega, Madison, Wis.) and XL1 Blue (Stratagene, La Jolla, Calif.) were used for plasmid propagation.

**Fermentor cultivation.** The defined medium of Vogel (40) was used, except that lactose (10 g/liter) was used instead of sucrose as the carbon source and (NH₄)₂SO₄ (1.65 g/liter) was used instead of NH₄NO₃ as the nitrogen source. Vogel's salts were prepared as a 50× solution and sterilized by filtration (pore size, 0.22 µm) filtration. The media for shake flask cultures contained Stabilize QM (methyl vinyl ether-maleic anhydride copolymer cross-linked with 1,9-deca-dien; ISP Technologies, Wayne, N.J.) or Junlon (18) to promote filamentous growth; the concentrations of Stabilize QM and Junlon used were 0.75 g/liter for cultures used for growth rate and enzyme determinations and 1.5 g/liter for precultures used for bioreactors. To prepare precultures, 40-mI batch cultures were grown in 250-mI Erlenmeyer flasks or 250-mI Nephlos flasks (36). The flasks were inoculated with 10³ spores/ml (final concentration). The cultures were incubated on a rotary shaker at 200 rpm (2, 25 cm) at 30°C. Fermentations were carried out in either an Applikon bioreactor (full working volume, 2.3 liters; FT Applikon Ltd., Twkesbury, United Kingdom) or in a B. Braun BIOSTAT M (full working volume, 2.1 liters; Sartorius BBI Systems, Mesungen, Germany) as previously described (42). The medium contained 10 g of lactose per liter as the sole carbon source. Cultures were inoculated with five 40-mI shake flask cultures which had been growing in medium containing 10 g of the same carbon source per liter for approximately 3 days. Fermentor cultures were maintained at 28 ± 1°C and pH 5.5 ± 0.1, agitated at 900 to 1000 rpm with three six-blade (diameter, 48 mm) Rushton turbine impellers, and aerated with 0.7 liter of air of culture -1 min -1. Foaming was controlled by adding a mixture of polypropylene glycols (PPG) having different molecular weights that included PPG 1025 (BDH, VWR International, Poole, United Kingdom), PPG 2025 (BDH, Poole, United Kingdom), and Foam Master PPG (mixed molecular weight; Henkel Performance Chemicals, Leeds, United Kingdom) at a ratio of 2:2:1 (41), if necessary. For cultures grown in the BIOSTAT M, the PPG mixture was added as an aseptic suspension (25%, vol/vol), while for cultures grown in the Applikon bioreactor it was added as a 100% suspension.

**Cloning and sequence analysis of bga1.** β-Galactosidases from the following fungi and bacteria were used for an alignment to identify conserved regions: A. niger (GenBank accession no. P29853), A. oryzae (5), P. canescens (GenBank accession no. Q12660), and Bacillus circulans (GenBank accession no. C5618). We used the degenerate primers 5'-GGGCGCGTCCCCTAAARTYGNTCNGGGAYGAG-3' and 5'-GGGGGATCTCATYRTCTYRTNKRTG-3', corresponding to the amino acid sequences QKYVTWDD and Q(P/I)ENEY, with BamHI restriction sites (underlined) at their 5′ ends for PCR amplification; QM9414 chromosomal DNA was used as the template. The following PCR reaction conditions were used: (i) 96°C for 10 min, after which 1 × of U enzyme (Dyana II; Finnzymes, Espoo, Finland) and 100 µl of reaction mixture was added; (ii) 96°C for 4 min; (iii) three cycles consisting of 96°C for 1 min, 37 or 42°C for 30 s, and 72°C for 1 min; (iv) 24 cycles consisting of 96°C for 1 min, 55°C for 1 min, and 72°C for 1 min; and (v) 4°C indefinitely. PCR products (500 bp) were PstI and SmaI-blunted and ligated into the SmaI site of pDBGA, resulting in pDBGAamdS. These ligated samples were diluted to 700 µl of reaction mixture, and 10 µl were added to 20 µl of 100 µM PNP-β-D-galactosidase and incubated in a one-step reaction mixture at 30°C for 10 min. The reaction was terminated by the addition of 3 µl of 0.05 M Na₂CO₃. The absorbance at 405 nm was measured in a microplate reader and reported as the amount of cell-bound enzyme.

**Enzyme assay.** β-Galactosidase activity was determined with o-nitrophenyl-β-D-galactopyranoside as the substrate. Cell extracts, supernatant, and cell wall-bound enzymes were diluted with 1 M NaCl and subjected to 50°C for 10 min to inactivate the enzyme. The resulting homogenate was then added to 300 µl of 100 µM β-mercaptoethanol, suspended, and homogenized by sonication 10 times for 30 s at 2°C, with intermittent 2-min cooling periods. The supernatant (average protein concentration, 8 to 15 mg/ml) was used as a cell extract for measuring intracellular β-galactosidase activity. After repeated washing of the remaining pellet with 0.1% Triton X-100, the cell debris was resuspended in 3 ml of citrate buffer (pH 5) per g (dry weight) of the original mycelium and was used as a source to measure cell wall-bound β-galactosidase activity.

**Fermentor cultivation.** The defined medium of Vogel (40) was used, except that lactose (10 g/liter) was used instead of sucrose as the carbon source. The mycelia were harvested by filtration through Miracloth (Caled) or a standard (500 to 10 mg/ml) in an Eppendorf tube for 1 h at 37°C, and the supernatant (average protein concentration, 8 to 15 mg/ml) was used as a cell extract for measuring intracellular β-galactosidase activity. After repeated washing of the remaining pellet with 0.1% Triton X-100, the cell debris was resuspended in 3 ml of citrate buffer (pH 5) per g (dry weight) of the original mycelium and was used as a source to measure cell wall-bound β-galactosidase activity.

**Determining of fungal growth and biomass.** To determine hyphal growth on agar plates, plates were inoculated with a small piece of agar in the center of each 11-cm plate. The biomass in submerged cultures was measured by filtering two 10-ml portions of culture onto prehydrated and preweighed Whatman no. 1 filter papers. The harvested biomass was dried to constant weight (70°C for at least 3 days or 30 min in a microwave oven at 260 W), after which each filter was washed with 20 ml of deionized water. Growth rates in bioreactors were estimated from the CO₂ output by using an
RESULTS

Cloning and characterization of bga1 and its protein product. A 5-kb genomic subclone, which included the complete structural gene, was isolated by hybridization to a probe based on conserved regions of fungal β-galactosidases. This subclone contains a 3,523-bp open reading frame interrupted by seven introns (55, 57, 75, 69, 66, 64, and 65 bp) encoding a 1,023-amino-acid polypeptide that includes a 20-amino-acid noncoding strand. Symbols: O, Cre1; □, Hap2/3/5; ◊, Ace1; O, AmyR; •, Msn2/4.

The bga1 sequence has been deposited in the GenBank database under accession number AJ549427.

FIG. 1. Presence of consensus binding sites for known fungal transcription factors in the bga1 upstream noncoding region. The positions are relative to the position of the translation start codon (ATG). The positions above the lines are the sites of the consensus sequences on the coding strand, and the positions below the lines are the sites on the noncoding strand. Symbols: O, Cre1; □, Hap2/3/5; ◊, Ace1; O, AmyR; •, Msn2/4.

Biochemical analyses. Protein concentrations were determined by the Bio-Rad protein assay (Bio-Rad Laboratories, Munich, Germany). The protocols described by Ausubel et al. (3) were used for sodium dodecyl sulfate-polyacrylamide gel electrophoresis (with 10% polyacrylamide gels) and Western blotting. Monoclonal antibodies were used to detect cellobiohydrolases CBHII/Cel6A and CBHII/Cel6A (24).

Nucleotide sequence accession number. The bga1 sequence has been deposited in the GenBank database under accession number AJ549427.

FIG. 2. Regulation of bga1 gene transcription during growth on various carbon sources of QM9414 (A) and RUT-C30 (B). Samples were obtained after 3 and 6 h of growth after transfer to different carbon sources (1%, wt/vol). In the case of lactose a sample was taken after 24 h of batch growth (conidial inoculum). Abbreviations: Gly, glycerol; Glc, D-glucose; Gal, D-galactose; Ara, L-arabinose; Xyl, D-xylose; Gol, galactitol; Aol, L-arabinitol; Xol, xylitol; Lac, lactose. 18S RNA served as a loading control.

REGULATION OF Β-GALACTOSIDASE OF H. JECORINA 853

β-GALACTOSIDASE OF H. JECORINA 853

and xylanase repressor Ace1 (AGGCA) (2) and the transcriptional activator AmyR (CGGN8CGG) (35). No consensus binding sites for XlnR, the A. niger transcriptional activator of xylanase and cellulase biosynthesis (38) which is also involved in regulation of A. niger lacA (8), or for Saccharomyces cerevisiae Gal4 (CGGN3CCG) (10), the transcriptional activator of the Leloir pathway genes, were found.

Regulation of bga1 gene transcription. We performed Northern analyses of the bga1 transcript during growth of H. jecorina on a variety of carbon sources (Fig. 2). The bga1 transcript was most abundant during growth of H. jecorina on L-arabinose and L-arabinitol and was present at lower levels during growth on D-galactose and D-xylose and their corresponding polys. The expression on lactose was low relative to that on D-galactose or D-xylose, and no transcript accumulated during growth on D-glucose and glyceral. Since these findings could be indicative of carbon catabolite repression, we also investigated bga1 transcription in the cre1 mutant RUT-C30 (17). In this Cre1-derepressed strain basal levels of the bga1 transcripts accumulated during growth on D-glucose, glyceral, and D-xylose, and high levels were found during growth on D-galactose and lactose, indicating that Cre1-dependent carbon catabolite repression interferes with bga1 transcription depending on the carbon source at either the basal or the induced level of transcription. Transfer to D-glucose together with L-arabinose or D-galactose showed that the presence of glucose interfered with the transcriptional activation only during growth on D-galactose.

Role of bga1 in growth on lactose. We produced a bga1 deletion mutant by replacing the coding region of bga1 with the A. nidulans acetamidase (amdS) gene in QM9414 and selecting for transformants that could grow on acetamide as a sole nitrogen source. These transformants were analyzed by Southern analysis (Fig. 3A). Hybridization with the fragment of bga1 which was replaced in the deletion vector by amdS gave a signal in QM9414 but not in the Δbga1 strains, confirming its deletion. On agar plates, the Δbga1 deletion strains grew at the wild-type rate with D-galactose as the carbon source but at lower rates with lactose or D-glucose. The effect observed with D-glucose was not due to ectopic insertion of the transforming DNA at other loci because the wild-type phenotype could be completely restored by retransformation of the bga1 deletion strains with the bga1 gene (data not shown).

We grew the Δbga1 strains in shake flasks and monitored the increase in biomass (Fig. 3B). In the presence of peptone, growth of the Δbga1 strain started at the same time (10 to 15 h...
after inoculation), and the growth rate was approximately constant throughout the incubation experiment. However, the biomass concentration of the \( H_9004 \) strain was somewhat less than one-half of the biomass concentration of the parent strain (2.3 versus 6.0 g/liter). The two strains also were grown in the absence of peptone in controlled fermentor cultures. In this case, the loss of function of \( bga1 \) was dramatic and resulted in a significantly delayed onset of growth on lactose (125 versus 40 h). The final decrease in biomass yield (2.5 versus 4.8 g/liter) was comparable to that in shake flasks, however.

**Activity of Bga1.** We compared the \( \beta \)-galactosidase activities in the culture supernatant, cell extract, and mycelial debris after homogenization of QM9414 and the \( \Delta bga1 \) strain after growth for 24 h on lactose. More than 95% of the total extracellular \( \beta \)-galactosidase activity of QM9414 was secreted into the culture supernatant, while only a small percentage was associated with the cell walls (0.86 versus 0.006 U/g [dry weight] of mycelium). Most of the activity present in the culture medium was lost in the \( \Delta bga1 \) mutant (0.07 U/g [dry weight] of mycelium), indicating that \( H. \) jecorina has a second \( \beta \)-galactosidase which accounts for \( \sim 10\% \) of the total extracellular \( \beta \)-galactosidase activity hydrolyzing aryl-\( \beta \)-galactoside. No intracellular \( \beta \)-galactosidase activity was detected during growth on lactose at either pH 5.0 or pH 7.0.

**Lactose-dependent induction of cellulase gene expression in the \( \Delta bga1 \) strain.** We cultivated QM9414 and the \( \Delta bga1 \) strain on lactose and measured the total cellulase and \( \beta \)-glucosidase activities and the accumulation of the cellobiohydrolase CBHI/Cel7A protein in the supernatant. The appearance of cellulase and \( \beta \)-glucosidase activities in the medium was delayed in the \( bga1 \) mutant, but the final levels were comparable when they were related to the biomass of the parent strain. Consistent with these data, the level of the CBHI/Cel7A protein that accumulated was only about one-half of the wild-type level in the \( \Delta bga1 \) strain. These findings suggested that loss of the \( bga1 \)-encoded \( \beta \)-galactosidase function does not have a major effect on cellulase gene expression. We measured the accumulation of the transcripts of two major cellulase genes, \( cbh1 \) and \( cbh2 \), in both strains (Fig. 3C). The levels of both cellulase transcripts that accumulated were about the same in the two strains, except at 24 h, when the \( cbh1 \) and \( cbh2 \) transcript levels were lower in \( \Delta bga1 \). This difference could have been due to
slower growth by the Δbgal strain on lactose. Thus, the induction of both genes—apart from some growth-related retardation—was not affected in the bgal deletion strain.

**Overexpression of bgal and cellulase formation.** We constructed a series of *H. jecorina* strains that expressed bgal under the expression signals of the *H. jecorina* *pk1* (pyruvate kinase-encoding gene) promoter region and the bgal terminator region and compared their β-galactosidase activities after 24 h of growth on glycerol. The different transformants produced between 3 and 18 U/g (dry weight). Therefore, the best overexpressing transformants had up to >30-fold-greater β-galactosidase activity than lactose-grown cultures of *H. jecorina* strains that expressed bgal on lactose (dry weight) and cellulase gene transcription. All three transformants had up to >30-fold-greater β-galactosidase activity than lactose-grown cultures of QM9414. Three of these transformants (PKI-BGA3, PKI-BGA7, and PKI-BGA13), which secreted different β-galactosidase activities (3, 5, and 12 U/g [dry weight], respectively), were grown on lactose in shake flasks and evaluated for cellulase formation and cellulase gene transcription. All three transformants had a significantly higher rate of growth on lactose plus peptone (0.27 to 0.29 g [dry weight]/h) and reached the final dry weight (6.4 g/liter) after ~50 h of cultivation (Fig. 4A). All three transformants also had the ability to induce cbh1 and cbh2 gene expression on lactose as a carbon source (Fig. 4B), although we observed induction on cellulase in a manner and at a level comparable to the manner and level in the parental strain (data not shown). We also grew strain PKI-BGA13 in the fermentor in the absence of peptone and observed similar results (i.e., a reduced initial lag phase and 24-h-earlier production of the maximal amount of biomass).

**DISCUSSION**

We identified a gene (*bgal*) of *H. jecorina* that encodes the major extracellular β-galactosidase during growth of the fungus on lactose. An alignment of the *H. jecorina* Bga1 protein sequence with the two β-galactosidases from *Neurospora crassa* (accession no. NCU00642.1 and NCUO4623.1) and the two β-galactosidases from *A. nidulans* (accession no. AN0756.2 and AN0989.2) demonstrated that the areas of similarity are distributed throughout the whole protein sequences. Thus, the β-galactosidases in *N. crassa* and *A. nidulans* are likely the result of a gene duplication, which appears to have been absent in *H. jecorina*. The N-terminal half (up to amino acid 370) of these β-galactosidases also is conserved in filamentous fungi and other organisms. The C-terminal half of these proteins is found only in two bacterial β-galactosidases (*Clostridium acetobutylicum* β-galactosidase [accession no. NP_349128.1] and *Streptomyces avermitilis* β-galactosidase [accession no. NP_829331.1]), but it is absent from the β-galactosidases of other bacteria, plants, and mammals in the National Center for Biotechnology Information database. The function of the C terminus in the fungal β-galactosidase proteins is therefore obscure, as no domains indicative of a special role could be identified in silico (Seiboth and Kubicek, unpublished data).

No intracellular β-galactosidase activity was found. The intracellular β-galactosidases of fungi are rather stable enzymes (12), and we have been able to extract a number of other more labile enzymes in active forms from *H. jecorina* without having to use protease inhibitors by the same method (e.g., oxidoreductases involved in Δxylose and Δ-arabinose metabolism). It is therefore unlikely that the lack of an intracellular β-galactosidase is due to proteolytic or other inactivation during extraction.

This finding is consistent with results of a TBLASTN search (Expect, 1e^-5) of the *H. jecorina* genome database with the intracellular β-galactosidase of *K. lactis* (accession no. P00723), a family 2 glycosyl hydrolase, as the query, which produced no hits. In contrast, the genomes of *A. nidulans* and *N. crassa* (http://www.broad.mit.edu/annotation/fungi/) each contain two putative family 2 β-galactosidases (accession no. AN3201.2, AN2463.2, NCU05956.1, and NCU00810.1).

The lack of an intracellular β-galactosidase in *H. jecorina* implies that lactose is hydrolyzed extracellularly. This conclusion is consistent with the preliminary finding that germinated spores of *H. jecorina* grown on lactose can take up Δ-glucose and Δ-galactose (the hydrolysis products of lactose) but not lactose (Vehmaanperä, unpublished data). However, genes encoding putative orthologs of the lactose permeases of *K. lactis* (accession no. P07921) are found in the genome databases of fungi, including *T. reesei* E value, 5e^-84), *A. nidulans* E value, 2e^-81), and *N. crassa* E value, 2e^-70). Thus, it will be interesting to see whether this gene is expressed during growth on lactose in *H. jecorina* and whether its gene product catalyzes the transport of lactose.

Genetic manipulation of Bga1 activity by deletion or overexpression perceptibly affects growth on lactose during the early stages of cultivation. This effect is even more dramatic in the Δbgal strain in the absence of peptone; however, there is no obvious correlation between changes in Bga1 activity and the growth rate on lactose. Reduction of the β-galactosidase activity by ~90% only halved the growth rate, while a >10-fold increase in activity only tripled it.

These results suggest the presence of additional β-galactosidases which either do not hydrolyze aryl-β-galactosides or have only very low activity with them. The residual 5% of β-galactosidase activity found in the Δbgal strain could result from a second β-galactosidase. A putative candidate was found in the *T. reesei* genome database (accession no. fg.V.1. C3000108), and this candidate showed a reasonable degree of identity to a β-galactosidase of *Bacteroides thetaiotaomicron* (accession no. AA078619.1; E value, 1e^-67) and in addition contained a signal peptide at its N terminus. An additional hit for a β-galactosidase was obtained in a TBLASTN search, but the nucleotide sequence of this contig was 100% identical to the DNA sequence of the *Haemophilus somnus* β-galactosidase/β-glucuronidase (accession no. ZP_0012279) and occurred on a very small contig. Therefore, we considered this match to be an artifact. Presumably, this second β-galactosidase has an unusual amino acid sequence, or its activity is a secondary activity of another glycosidase.

The occurrence of a β-galactosidase in a saprophytic ascomycete like *H. jecorina* is somewhat paradoxical, as lactose does not occur in its natural environment, and the induction caused by lactose may be artificial. It is more likely that plant polysaccharides containing β-galactosidic linkages are the true substrates for the β-galactosidase. These polysaccharides also may contain Δ-arabinose, since bgal expression was triggered by both Δ-galactose and Δ-arabinose. In *A. niger* the extracellular β-galactosidase-encoding gene *lacA* was shown to be induced by the plant cell wall heteropolysaccharide pectin and several pectin monomers, including Δ-galacturonic acid,

1- 

t-arabinose, and D-galactose, indicating that it may be involved in pectin degradation (9).

Overexpression of the bga1 gene product, but not its deletion, eliminated cellulase gene expression on lactose. This result suggests that increased β-galactosidase activity interferes with cellulase induction. One simple explanation for this finding is that the β-galactosidase activity eliminates the inducer. However, we have no evidence that lactose is the inducer, and the lack of intracellular β-galactosidase activity, which is necessary for intracellular lactose catabolism and the termination of induction, argues against this possibility. Alternatively, increased concentrations of lactose hydrolysis products (i.e., D-glucose and D-galactose), which accumulate in the medium, could result in catabolite repression of cellulase gene expression. However, the carbon catabolite repression of cbh1 and other cellulase genes is only partial (45), and carbon catabolite repression alone should not result in a complete loss of cbh1 gene transcription, like that seen in the cre1 repression alone should not result in a complete loss of other cellulase genes is only partial (45), and carbon catabolite repression of H. jecorina cre1 gene product, but not its dele-
tion, eliminated cellulase gene expression on lactose. This result suggests that increased β-galactosidase activity interferes with cellulase induction. One simple explanation for this finding is that the β-galactosidase activity eliminates the inducer. However, we have no evidence that lactose is the inducer, and the lack of intracellular β-galactosidase activity, which is necessary for intracellular lactose catabolism and the termination of induction, argues against this possibility. Alternatively, increased concentrations of lactose hydrolysis products (i.e., D-glucose and D-galactose), which accumulate in the medium, could result in catabolite repression of cellulase gene expression. However, the carbon catabolite repression of cbh1 and other cellulase genes is only partial (45), and carbon catabolite repression alone should not result in a complete loss of cbh1 gene transcription, like that seen in the bga1-overexpressing mutants. Also, growing the H. jecorina cre1 loss-of-function strain RUT-C30 in the simultaneous presence of equimolar concentrations of D-glucose and D-galactose (S. Gyamphi and C. P. Kubicek, unpublished data) or D-galactose alone (30) does not result in cellulase production, which makes Cre1-dependent carbon catabolite repression a less likely explanation.

Another possible explanation is that D-galactose uptake could be inhibited by D-glucose. H. jecorina transports D-galacto-
tose with a general hexose transporter that can be inhibited by an excess of other hexoses (e.g., D-glucose and D-mannose) (Vehmaanperä, unpublished). However, D-glucose and D-galactose are present in the medium at comparable concentrations, and the affinities of the transporter for them are in the same concentration range, so a complete block of D-galactose uptake by D-glucose uptake is unlikely.

We recently showed that eliminating the galactokinase step in the Leloir pathway also eliminates cellulase induction by lactose, although growth on lactose still occurs (30). We interpreted these results to mean that either D-galactose, bound to galactokinase, or D-galactose-1-phosphate was the inducer of cellulase formation on lactose. We also suggested that this induction occurred only at a narrow range of concentrations of either of these intermediates, because D-galactose itself does not induce cellulase gene expression, even in a Cre1-negative background. This model is also consistent with the present data if the overexpression of bga1 influences the intracellular steady-state levels of either D-galactose or D-galactose-1-phosphate, which leads to a shutdown of cellulase transcription. Although the Leloir pathway genes of H. jecorina are not subject to glucose repression (30, 31), which may take place because of the increased rate of lactose hydrolysis, competition for substrates and coenzymes (e.g., ATP) may occur.

The data presented in this paper show that the H. jecorina bga1-encoded β-galactosidase activity has a major impact on the growth rate during lactose-based fermentations and on the performance of cellulase formation by H. jecorina in this process. Consequently, further attempts to manipulate the expres-
sion of genes involved in this process are needed to improve the production rate and yield of mutant strains on an industrial scale.

ACKNOWLEDGMENTS

This study was supported by the Fifth (EC) Framework program (Quality of Life and Management of Living Resources; projects EU-
ROFUNG 2 and OILK3-1999-07129) and by grant P 16143 from the Austrian Science Foundation to C.P.K. The H. jecorina/ T. reesei genome sequencing project was funded by the United States Department of Energy.

We thank Arja Mäntylä for useful discussions.
