Received 27 November 2004/Accepted 20 December 2004

The ergot alkaloids are a family of indole-derived mycotoxins with a variety of significant biological activities. Aspergillus fumigatus, a common airborne fungus and opportunistic human pathogen, and several fungi in the relatively distant taxon Clavicipitaceae (clavicipitaceous fungi) produce different sets of ergot alkaloids. The ergot alkaloids of these divergent fungi share a four-member ergoline ring but differ in the number, type, and position of the side chains. Several genes required for ergot alkaloid production are known in the clavicipitaceous fungi, and these genes are clustered in the genome of the ergot fungus Claviceps purpurea. We investigated whether the ergot alkaloids of A. fumigatus have a common biosynthetic and genetic origin with those of the clavicipitaceous fungi. A homolog of dmaW, the gene controlling the determinant step in the ergot alkaloid pathway of clavicipitaceous fungi, was identified in the A. fumigatus genome. Knockout of dmaW eliminated all known ergot alkaloids from A. fumigatus, and complementation of the mutation restored ergot alkaloid production. Clustered with dmaW in the A. fumigatus genome are sequences corresponding to five genes previously proposed to encode steps in the ergot alkaloid pathway of C. purpurea, as well as additional sequences whose deduced protein products are consistent with their involvement in the ergot alkaloid pathway. The corresponding genes have similarities in their nucleotide sequences, but the orientations and positions within the cluster of several of these genes differ. The data indicate that the ergot alkaloid biosynthetic capabilities in A. fumigatus and the clavicipitaceous fungi had a common origin.

† This paper is published with the approval of the Director of the Division of Plant & Soil Sciences, West Virginia University, Morgantown, West Virginia 26506-6058.

Festuclavine, one of the ergot alkaloids produced by A. fumigatus, was first described from Claviceps purpurea (6, 7) and has also been detected in Neotyphodium spp. (15, 19). However, none of the fumigaclavines produced by A. fumigatus has been detected in a member of the Clavicipitaceae. Likewise, the end products of the Claviceps spp. and Neotyphodium spp. pathways (ergopeptines and lysergic acid amides) have not been found in A. fumigatus. This distribution of alkaloids is consistent with the hypothesis that early steps of the ergot alkaloid pathways are shared by these diverse fungal species but the later portions of the pathways are different in A. fumigatus and the clavicipitaceous fungi. The ergot alkaloid pathway is relatively long and may have alternate branches or spurs in some ergot alkaloid producers (7, 8, 14, 15). Functions of three genes involved in the ergot alkaloid pathway have been demonstrated by gene knockout. The dmaW gene encoding dimethylallyltryptophan synthase (DMAT synthase) was knocked out in Neotyphodium sp. strain Lp1, an endophyte of perennial ryegrass (29). Loss of all ergot alkaloids in the knockout mutant indicated that dmaW controls the determinant step in the ergot alkaloid pathway. A gene encoding lyseryl peptide synthetase 1 (LPS1), one of two components of the lyseryl peptide synthetase complex responsible for assembly of ergopeptines from lysergic acid and three amino acids (20, 28), was also knocked out in Neotyphodium sp. strain Lp1 (16). LPS1-deficient knockout mutants failed to produce ergopeptines and simple amides of lysergic acid but still produced clavine ergot alkaloids (15, 16). A gene encoding lyseryl peptide synthetase 2 (LPS2), the lyseryl acid-activating component of the lyseryl peptide synthetase complex, has been cloned and knocked out in C. purpurea, resulting in the loss of ergopeptines from the knockout mutant (5).
Genes encoding DMAT synthase, LPS1, and LPS2 are clustered within ~32 kb of each other in the genome of *C. purpurea* (5, 25). Moreover, at least six additional genes that encode activities likely to be required for ergot alkaloid production are interspersed in this cluster with the ergot alkaloid biosynthesis genes (5, 25, 26). Analysis of mRNAs from five of the clustered genes indicate they are expressed in cultures grown under conditions conducive to ergot alkaloid production but are not expressed under repressive conditions (5). Such clustering and common regulation of secondary metabolite biosynthetic pathway genes are common in fungi (9, 27).

Our objective in this study was to determine whether the ergot alkaloids of *A. fumigatus* had a common biosynthetic origin with those of the clavicipitaceous fungi by identification and functional analysis of the *dmaW* gene controlling the determinant step in the pathway and by comparison of sequences flanking *dmaW* in *A. fumigatus* and *C. purpurea*.

**MATERIALS AND METHODS**

**Fungi and culture conditions.** *A. fumigatus* isolate WVU1943 (=FGSC A1141) from a parakeet lung is described in the accompanying paper (13) and isolate WVU1944 from a parakeet lung is described in the accompanying paper (13). Isolates were maintained on potato dextrose agar (PDA) (20 g/liter dehydrated mashed potatoes [Ishihara Spuds; Pillsbury, Minneapolis, MN], 20 g/liter glucose, 15 g/liter agar [Bacto agar; Difco, Detroit, MI]) at room temperature or at 37°C. Cultures for analysis of ergot alkaloids were grown on PDA at 37°C. For preparation of DNA or protoplasts, the fungus was cultured overnight in 15 ml of potato dextrose broth (Difco) in a deep petri dish (depth, 20 mm; diameter, 100 mm; Fisher Scientific, Pittsburgh, PA) on an orbital shaker at 37°C and 150 rpm. Cultures were inoculated by lightly dusting the medium with conidia that had adhered to a petri dish lid formerly covering a mature culture. In mock inoculations, an average of 1.2 × 10^6 conidia per petri dish was deposited by this inoculation method.

**Analysis of the *A. fumigatus* genome for ergot alkaloid biosynthesis genes.** *A. fumigatus* preliminary sequence data were obtained from The Institute for Genomic Research website (http://www.tigr.org). All *A. fumigatus* sequences described in this paper are located on assembly 92 (chromosome 2, formerly assembly 72) between nucleotides 2804958 and 2926335. The presence of sequences in the *A. fumigatus* genome that are similar to known or putative ergot alkaloid biosynthesis genes was assessed by application of the tblastn algorithm (1) at the National Center for Biotechnology Information website (www.ncbi.nlm.nih.gov) with the deduced protein sequences of DMAT synthase of *Claviceps fusiformis* (24) and LPS1 of *Neotyphodium loli (16)* or *C. purpurea* (26) as query sequences. The nature of genes linked to the ergot alkaloid biosynthesis genes or candidate gene sequences was investigated by retrieving contiguous 2-kb segments of DNA from the *A. fumigatus* genome and querying the nonredundant protein database of the National Center for Biotechnology Information with these sequences by application of the blastx search algorithm (1).

**Knockout and complementation of *dmaW* in *A. fumigatus*.** Fungal DNA for amplification by PCR was isolated by using the Gene Clean Spin protocol (Bio 101, Vista, CA). An internal fragment of *A. fumigatus* *dnaW* (encoding amino acids 136 to 352 of the predicted 497-amino-acid product) was amplified by PCR with primers *dnaW* forward (5'-TTGATCGGATGGTGCCTGCG-3') and *dnaW* reverse (5'-CGTCTGACCGGAGGCTTGAC-3') and *dmaW* reverse (5'-CGTTGACCGGAGGCTTGAC-3') and *dmaW* reverse (5'-CGTTGACCGGAGGCTTGAC-3') and *dmaW* reverse (5'-CGTTGACCGGAGGCTTGAC-3') and *dnaW* forward (5'-AGCTATGACCATGATTACGCCA-3') and *dnaW* reverse (5'-AGCTATGACCATGATTACGCCA-3'). 50-μl PCR mixtures contained 50 mM KCl, 10 mM Tris-HCl (pH 9.0), 0.1% (vol/vol) Triton X-100, 1.5 mM MgCl2, 200 μM of each deoxynucleotide triphosphate, 1 μM of each primer, and 2.5 U of Taq DNA polymerase (Promega, Madison, WI), which was added once the thermocycler reached 95°C in the initial denaturing period. The reaction began with an initial denaturation step consisting of 2.5 min at 95°C, which was followed by 35 cycles of 1 min at 94°C, 1 min at 55°C, and 1 min at 72°C. The 651-bp *dnaW* PCR product was ligated into pCR2.1 (Invitrogen, Carlsbad, CA) based on T/A overhangs and was transformed into chemically competent Escherichia coli cells. The resulting 4.5-kb gene knockout construct, pDMAT1, was linearized at a unique PpuMI site in the *dnaW* coding sequences prior to transformation of *A. fumigatus*.

Protoplasts of *A. fumigatus* were prepared by the method of Murray et al. (11), except that 5 mg/ml of Driselase (InterSpx, Foster City, CA), 1.3 mg/ml Novozyme 234 (InterSpx), and 25 μg/ml chitinase (Sigma, St. Louis, MO) were used as lysing enzymes. Coformation of the protoplasts with PpuMI-linearized pDMAT1 and the hygromycin resistance-conferring plasmid pMcoX (12), which had been linearized at a unique NotI site, was performed as previously described (16), but with 2 μg of each DNA in 10 μl of water. Considering the relative differences in the sizes of the cotransformed molecules, the equal masses introduced corresponded to an approximately twofold molar excess of the gene knockout construct (pDMAT1, 4.5 kb) relative to the selectable marker (pMcoX, 8.8 kb). The transformation mixture was divided into six aliquots and plated on regeneration medium containing 300 μg/ml hygromycin (Calbiochem, La Jolla, CA) as previously described (16). Transformation plates were incubated at 37°C for 2 days, and hygromycin-resistant colonies were transferred onto PDA plates containing 400 μg/ml hygromycin.

Transformants were screened for homologous recombination of pDMAT1 with the native *dmaW* gene by PCR (using the conditions described above, except that the annealing temperature was 57°C) with primer UR (5'-TGGTTAAGCTTGCGGCTGTC-3') and primer reverse (5'-AAGTGAAGTCGGCGACCTTTCTGACCGGAGGCTTGAC-3'), which annealed to *dmaW* sequences near the 3' end of the gene and flanking the intended site of integration (Fig. 1A). Transformants yielding a fragment of the expected size for a gene knockout at *dmaW* (1.2 kb) were purified to nuclear homogeneity by culturing them from individual, germinated conidia. Single-spore colonies were again screened by PCR (using the conditions described above but with an annealing temperature of 57°C) with primers UR (5'-TGGTTAAGCTTGCGGCTGTC-3') and primer 35S (5'-TGTGTTAAGCTTGCGGCTGTC-3'), which annealed to *dnaW* sequences near the 5' end of the gene and flanking the intended site of integration (Fig. 1A). In this way, the 5' and 3' borders of the integration site were analyzed by PCR. Candidate gene knockout strains also were screened with primers 5S and 3S under the PCR conditions described above with an annealing temperature of 57°C. Finally, transformants producing fragments of the expected sizes in the PCR analyses were further analyzed by Southern hybridization as described below.

Fungal DNA for Southern blot hybridization was digested with *SspI* and size fractionated by electrophoresis through 0.8% agarose, and transferred to a Bio-dyne A nylon membrane (Pall-Gelman Sciences, Ann Arbor, MI) by capillary action with 20× SSC (1× SSC is 150 mM NaCl plus 15 mM trisodium citrate) as the transfer medium. A *dnaW* probe was labeled with digoxigenin (DIG)-dUTP by PCR amplifying wild-type genomic DNA with primers *dnaW* forward and *dmaW* reverse (see above). The PCR conditions were the same as those described above except that a 1× DIG DNA labeling mixture (Roche Applied Science, Indianapolis, IN) was used instead of the standard deoxynucleoside triphosphates. Hybridization was performed at 65°C in 5× SSC, 0.1% (wt/vol) N-lauroylsarcosine, 0.2% (wt/vol) sodium dodecyl sulfate, 1% (wt/vol) blocking reagent (Roche), 100 mM NaCl (pH 7.5). The final washes were with 0.5× SSC-0.1% sodium dodecyl sulfate at 65°C. Bound probe was detected with anti-DIG antibody, followed by chemiluminescence performed by the standard method (DIG Manual; Roche Applied Science, Indianapolis, IN).

An ergot alkaloid-deficient *dnaW* knockout strain was complemented with a full-length *dnaW*-containing fragment produced by PCR with primers 5'-AGTTGCTGCGGAGGCTTGAC-3' and 5'-CCCTCGAGCGGAGGCTTGACG-3', which primed amplification of a 3.4-kb fragment containing the entire *dmaW* coding sequence along with 784 bp of the 5' flanking sequence and 1,123 bp of the 3' flanking sequence. The PCR conditions were the same as those described above except that the annealing temperature was 57°C and the extension time at 72°C was 3 min 20 s. The PCR product was cotransformed into a *dmaW* knockout strain along with phycocyanin resistance-conferring plasmid pBC-phkho (22) (Fungal Genetics Stock Center, University of Missouri-Kansas City, Kansas City, MO). Selection was on complete regeneration medium containing 100 μg/ml hygromycin.

**Analysis of ergot alkaloids.** Ergot alkaloids from conidia produced on PDA plates were extracted with 80% methanol and analyzed by high-performance liquid chromatography with fluorescence detection as described in the accompanying paper (13).

**RESULTS**

**Identification and analysis of a *dmaW* homolog in *A. fumigatus*.** A search of the *A. fumigatus* genome database revealed an excellent match for *C. fusiformis* *dmaW*, which encodes DMAT synthase, the enzyme that catalyzes the first step in the ergot alkaloid biosynthetic pathway. Genes encoding DMAT synthase, LPS1, and LPS2 are common in fungi (9, 27).
alkaloid pathway in clavicipitaceous fungi. The deduced *A. fumigatus* DMAT synthase was 50% identical to the DMAT synthase from *C. fusiformis* (24), 53% identical to the DMAT synthase from *C. purpurea* (26), and 59% identical to the DMAT synthase from *Neotyphodium* sp. strain Lp1 (29). The *A. fumigatus* *dmaW* sequence contained a single intron at a position identical to the position of the single introns in the *dmaW* genes isolated from the *Claviceps* and *Neotyphodium* spp. (data not shown).

A gene knockout construct, designed to integrate at *dmaW* by a single crossover (Fig. 1), was targeted to the *dmaW* locus in 3 of 25 hygromycin-resistant transformants analyzed (Fig. 1 and 2). PCR analysis of the 5′ and 3′ junctions of the native *dmaW* gene and the integrated gene knockout construct yielded fragments of the expected length for homologous recombination of such a construct at *dmaW* (Fig. 1B and C). PCR amplification of the gene knockout strains with primers 5S and 3S, spanning the site of recombination, failed to yield the 1.2-kb product only from the strain with a disrupted *dmaW* gene. Although additional amplicons can be predicted from duplicate annealing sites for primers UF and UR, which result from the multiple integrations of pDMAT1, these theoretical amplicons are much too large to be amplified with the PCR conditions and reagents used in this study. The relative mobilities of relevant fragments (in kilobases) of BstEII-digested bacteriophage lambda are indicated on the left in panels B and C.

![Diagram](https://example.com/diagram.png)

**FIG. 1.** (A) Diagrammatic representation of homologous recombination at *dmaW*. In the wild-type (wt) diagram, F and R are annealing sites for primers *dnaW* forward and *dnaW* reverse, respectively, which amplify an internal portion of *dnaW*. The gene knockout construct pDMAT1, containing the internal fragment of *dnaW*, was linearized at a unique PpuMI site internal to *dnaW* prior to transformation. The diagram labeled ko represents the *dnaW* locus with three copies of pDMAT1 integrated in tandem, disrupting *dnaW*. UF, annealing site for a primer derived from universal primer sequences in the vector; 3S, annealing site for a primer flanking the 3′ border of the site of integration; UR, annealing site for a primer derived from reverse primer sequences in the vector; 5S, annealing site for a primer flanking the 5′ border of the site of integration. (B) PCR from primers UR and 5S amplified the expected 852-bp band from a strain carrying the disrupted *dnaW* allele but not from the wild-type isolate. (C) PCR from primers UF and 3S amplified the 1.2-kb product only from the strain with a disrupted *dnaW* gene. Although additional amplicons can be predicted from duplicate annealing sites for primers UF and UR, which result from the multiple integrations of pDMAT1, these theoretical amplicons are much too large to be amplified with the PCR conditions and reagents used in this study. The relative mobilities of relevant fragments (in kilobases) of BstEII-digested bacteriophage lambda are indicated on the left in panels B and C.

The *dnaW* knockout strains did not produce any of the known ergot alkaloids (Fig. 3). Additional peaks, including uncharacterized molecules eluting at 55.5 min and 56 min (Fig. 3) and a minor peak eluting at 32.8 min (evident only when the traces were viewed at much higher sensitivity), also were eliminated by knockout of *dnaW*. The peak eluting at 32.8 min is proposed to contain one or more of the isomers of chanoclavine based on a measured molecular mass of 256 and coelution with a chanoclavine standard. The molecules that eluted later were not characterized further.

Transformation of strain *dnaW* ko6 with a DNA fragment containing the entire *dnaW* coding sequences plus 784 bp of 5′ flanking sequences and 1,123 bp of 3′ flanking sequences restored the ability to produce ergot alkaloids (Fig. 3). The complementing fragment was determined to have integrated ectopically, because the gene knockout construct was retained at the native *dnaW* locus (data not shown). All known *A. fumigatus* ergot alkaloids were produced in the complemented strains (Fig. 3).

**Genes clustered with *dnaW* in *A. fumigatus*.** Database searches with five *C. purpurea* gene sequences, which in addi-
tion to dmaW have been proposed to be involved in ergot alkaloid biosynthesis (but which have not yet been functionally analyzed), identified potential homologs clustered with each other and with the dmaW homolog of A. fumigatus (Fig. 4). These genes included two putative oxidoreductase-encoding genes identified as cpox1 and cpox2, as well as a catalase-encoding gene and two unidentified open reading frames (labeled orfA Cp and orfB Cp), whose sequences and close linkage with dmaW are conserved in C. purpurea (25, 26) and C. fusiformis (10). Despite the similarity in the composition of the clusters of genes associated with dmaW in A. fumigatus and C. purpurea, the physical arrangement in terms of the orientation and order of genes within the cluster was different in the two fungi (Fig. 4).

Analysis of additional sequences clustered near dmaW of A. fumigatus revealed several other genes that may encode enzymes in the ergot alkaloid pathway (Fig. 4). These sequences include similar to the sequences encoding cytochrome P450 monoxygenases, a flavin adenine dinucleotide-dependent monoxygenase, and short-chain alcohol dehydrogenases. Additional sequences whose deduced functions are consistent with roles in formation of the side chains that are different in the three fumigaclavines also were identified. These sequences include sequences encoding several monoxygenases or hydroxylases and an O-acetyltransferase and a divergent dmaW-like (prenyl transferase) gene. The predicted product of the divergent dmaW-like gene exhibited 25% identity with the deduced product of A. fumigatus dmaW required for ergot alkaloid biosynthesis and 26%, 25%, and 27% identity with the deduced products of the dmaW genes of C. purpurea, C. fusiformis, and Neotyphodium sp. strain Lp1, respectively.

Distal to orfB Cp in A. fumigatus is a metalloprotease-encoding gene and a retrotransposon-rich region, after which the assembly ends (within 36 kb). Proximal to the A. fumigatus cluster are several genes encoding unknown hypothetical proteins, a few additional genes encoding deduced products also potentially involved in alkaloid biosynthesis, and interspersed genes for which no role in ergot alkaloid biosynthesis has been deduced.

**DISCUSSION**

Our results demonstrate that the genome of A. fumigatus contains a homolog of dmaW that is required for ergot alkaloid biosynthesis. The loss of all known ergot alkaloids upon inactivation of dmaW in A. fumigatus indicates that this gene controls the determinant step in the ergot alkaloid pathway of A. fumigatus, as it does in the clavicipitaceous fungus Neotyphodium sp. strain Lp1 (29). Moreover, in the A. fumigatus genome, dmaW is clustered with genes that are similar to and extend the ergot alkaloid gene cluster observed in the ergot fungus C. purpurea. Collectively, the data indicate a common
biosynthetic and genetic origin for the ergot alkaloids of \textit{A. fumigatus} and of the ergot alkaloid-producing members of the \textit{Clavicipitaceae}.

Each of the three gene knockout strains investigated contained three or more copies of the knockout construct integrated at \textit{dmaW}. The multiple integrations may have resulted from either or both of two modifications of the more typical gene knockout strategy that we used in this experiment. First, the knockout construct was introduced by cotransformation at two times the molar concentration of the selectable marker construct. Second, the knockout was created by integrating an internal fragment of the gene via a single crossover, a strategy that has resulted in multiple integrations in previous studies with other fungi (2, 17, 18, 21).

This approach was chosen for two reasons. The knockout construct can be easily prepared in a single cloning step, which should facilitate similar analyses of many of the genes in the cluster. Also, since we intended to complement the mutation in the wild-type strains in the present study indicated that conidia of \textit{A. fumigatus} also contain small quantities of chanoclavine. This result is not surprising since chanoclavine is an early pathway intermediate in the biosynthesis of all known ergot alkaloids and it accumulates to various degrees in different ergot alkaloid producers (7, 8, 14, 15, 25).

Among the ergot alkaloids produced by \textit{A. fumigatus}, only festuclavine and chanoclavine have been detected in any of the clavicipitaceous ergot alkaloid producers that have been studied (6, 7, 15, 19). Conversely, the ergot alkaloid-producing members of the \textit{Clavicipitaceae} produce numerous ergot alkaloids that are not found in \textit{A. fumigatus}. These include the ergopeptides (tripeptide derivatives of lysergic acid) and simple amides of lysergic acid (such as ergonovine and ergine). The production of both the ergopeptide and simple amide classes of ergot alkaloids is dependent upon the activities or products of lysergyl peptide synthetases (5, 15, 16). Based on the ergot alkaloid profiles and sequences clustered with dmaW the presence of \textit{A. fumigatus} and \textit{C. purpurea}, we hypothesize that the early stages of the pathway are shared by \textit{A. fumigatus} and \textit{C. purpurea} but that later steps in the pathways differ in the two fungi.

The ergot alkaloid pathways of \textit{A. fumigatus} and \textit{C. purpurea} probably share several steps in addition to the determinant step catalyzed by DMAT synthase. The cluster of genes immediately around dmaW in \textit{A. fumigatus} contains five hypothetical genes that are highly similar to genes previously hypothesized to be involved in the early stages of the ergot alkaloid pathway of \textit{C. purpurea} (5, 25, 26). These genes include the following: a sequence labeled orfB, which encodes a product similar to a methyl transferase, an activity required for the second step in the pathway; two genes (cpox1 and cpox2) encoding oxidoreductase that may catalyze early steps in the pathway (7, 14,
25); a sequence labeled orfA, for which a biochemical function has not been proposed; and a catalase-encoding gene. A function for the catalase in ergot alkaloid biosynthesis is not obvious. One possibility is that the catalase acts peroxidatively to oxidize the primary alcohol of chanoclavine to the corresponding aldehyde, which is a step required prior to cyclization of the fourth ring of the basic four-member ergoline ring system (7, 8, 14).

Interestingly, the orientation and position of three members of this putative core set of genes differ in the gene clusters of the two fungi, suggesting that numerous recombination events occurred after divergence of the lineages of these two fungi. Alternatively, if the cluster had been acquired by horizontal gene transfer, then the dissimilarities indicate that any such transfer was ancient and not recent.

We propose that after a shared early stage, the ergot alkaloid pathways of *A. fumigatus* and the clavicipitaceous fungi diverge and yield different end products. Cultures of *A. fumigatus* do not contain detectable levels of the later products of the pathway, such as lysergic acid or lysergyl derivatives such as ergopeptines (13). Consistent with this hypothesis, searches with fragments of genes encoding LPS1 (required for the assembly of the ergopeptine class of ergot alkaloids) from *N. lolii* (16) or *C. purpurea* (26) and LPS2 (required for activating lysergic acid for peptide formation) from *C. purpurea* (5) produced only low-level matches to miscellaneous peptide synthetase genes in the *A. fumigatus* genome. The degree of identity observed was typical of the degrees of identity among peptide synthetases catalyzing the assembly of unrelated nonribosomally synthesized peptides in fungi (27), and none of the low-level matches was located near the *dmaW* gene.

Conversely, the *A. fumigatus* cluster contained genes not found in the *C. purpurea* cluster. Some of these hypothetical genes encode functions that we hypothesize to be involved in the later steps of the *A. fumigatus* pathway leading from festucaline to the fumigaclines, which are not produced by *C. purpurea*. For example, the gene of the protein in the *A. fumigatus* cluster predicted to encode an O-acetyltransferase may function in acetylating fumigacline B to fumigacline A. The unusual, alternate *dmaW* gene (labeled alt *dmaW* in Fig. 4) may control the prenylation of fumigaciline A to fumigaciline C. The lack of ergot alkaloids in the mutant containing a knockout at the typical *dmaW* gene demonstrates that the highly divergent *dmaW*-like prenyltransferase gene found in the cluster is not functionally redundant with *dmaW* and thus may catalyze another prenylation step.

The ergot alkaloid gene cluster of *C. purpurea* and the cluster of genes containing *dmaW* in *A. fumigatus* appear to have a common origin. The cluster of genes in *A. fumigatus* lacks the large peptide synthetase gene found in the *C. purpurea* cluster, revealing several additional genes potentially involved in ergot alkaloid production. Systematic gene knockouts and their characterization should allow definition of the early (and probably shared) steps of the ergot alkaloid pathway, several of which have been difficult to characterize biochemically in *C. purpurea* (7, 8, 14). Ergot alkaloid-deficient mutants, such as the *dmaW* knockout, may be useful for assessing the contribution of ergot alkaloids to virulence to animals or potential contributions of the alkaloids to the success of *A. fumigatus*.

**ACKNOWLEDGMENTS**

This work was supported by USDA-NRI grant 2001-35319-10930 and Hatch funds. Sequencing of the *A. fumigatus* genome was funded by National Institute of Allergy and Infectious Disease grant U01 AI 48830 to David Denning and William Nierman, the Wellcome Trust, and Fondo de Investigaciones Sanitarias.

We thank Caroline Machado, Christopher Schardl, and Mark Farman (University of Kentucky) for access to data and helpful suggestions and Brian Tapper (AgResearch Limited, New Zealand) and Miroslav Flieger (Czech Academy of Sciences) for the chanoclavine standard. Preliminary sequence data for the *A. fumigatus* genome were obtained from The Institute for Genomic Research (http://www.tigr.org). The assistance of Bill Nierman and Natalie Fedorova with questions concerning the data is greatly appreciated.
