Received 11 July 2010/Accepted 11 January 2011

Sand bedding material is frequently used in dairy operations to reduce the occurrence of mastitis and enhance cow comfort. One objective of this work was to determine if sand-based bedding also supported the microbiologically based suppression of an introduced bacterial pathogen. Bedding samples were collected in summer, fall, and winter from various locations within a dairy operation and tested for their ability to suppress introduced populations of *Escherichia coli* O157:H7. All sources of bedding displayed a heat-sensitive suppression of the pathogen. Differences in suppressiveness were also noted between different samples at room temperature. At just 1 day postinoculation (dpi), the recycled sand bedding catalyzed up to a 1,000-fold reduction in *E. coli* counts, typically 10-fold greater than the reduction achieved with other substrates, depending on the sampling date. All bedding substrates were able to reduce *E. coli* populations by over 10,000-fold within 7 to 15 dpi, regardless of sampling date. Terminal restriction fragment length polymorphism (T-RFLP) analysis was used to identify bacterial populations potentially associated with the noted suppression of *E. coli* O157:H7 in sand bedding. Eleven terminal restriction fragment lengths (TRFs) were overrepresented in paired comparisons of suppressive and nonsuppressive specimens at multiple sampling points, indicating that they may represent environmentally stable populations of pathogen-suppressing bacteria. Cloning and sequencing of these TRFs indicated that they represent a diverse subset of bacteria, belonging to the *Cytophaga-Flexibacter-Bacteroidetes*, *Gammaproteobacteria*, and *Firmicutes*, only a few of which have previously been identified in livestock manure. Such data indicate that microbial suppression may be harnessed to develop new options for mitigating the risk and dispersal of zoonotic bacterial pathogens on dairy farms.

*Escherichia coli* O157:H7 is a food-borne pathogen of global public health significance (39), so understanding the factors affecting its survival in the environment is critical to minimize its impact on human health. Cattle manure is a major reservoir of *Escherichia coli* O157:H7. However, the factors contributing to bovine colonization and shedding of *E. coli* O157:H7 are poorly understood, and there are still very few tools available to control these zoonotic bacteria in cattle populations (23). Early epidemiological studies in livestock populations showed that individual farms often tended to maintain either a high or a low prevalence of *E. coli* O157:H7 over time (18, 45). This relative stability of pathogen prevalence on individual farms has been interpreted to be an indication for a role of stable farm management factors in governing the relative abundance of *E. coli* O157:H7 in cattle populations. In addition, the prevalence of *E. coli* O157:H7 is seasonally modulated. Most studies indicate a peak in prevalence in cattle that occurs in summer and is coincident with the seasonal peak in human illnesses (3, 5, 11, 12, 17).

Interestingly, there are several similarities in the patterns of *E. coli* O157:H7 carriage by dairy cattle and cases of mastitis caused by *E. coli* (and other coliforms) in cows. Stanford et al. (46) demonstrated an association between somatic cell counts, a mastitis indicator, and *E. coli* O157:H7 prevalence on dairy farms. As with the *E. coli* O157:H7 prevalence in cattle, the incidence of coliform mastitis also fluctuates in the same seasonal manner (44). The primary source of mastitis-causing coliforms is the bedding material, and the incidence of coliform mastitis is influenced by the type of bedding material used (sand or sawdust) (19, 33, 36, 56). Moreover, LeJeune and Kauffman (22) demonstrated that dairy herds bedded on sawdust showed a significantly greater prevalence of *E. coli* O157:H7 than herds bedded on sand. Thus, because contaminated livestock bedding can significantly increase *E. coli* O157:H7 carriage in cattle, successful interventions targeted at this stage of production could reduce prevalence on the farm and have positive downstream impacts on human health.

Pathogen suppression can be mediated by a variety of biotic and abiotic soil factors. In solid-phase media, pathogens are the target of inhibitory soil functions that prevent them from expressing pathological effects to their full potential (3). General suppression of plant pathogens is mediated by the quantity and quality of soil organic matter that supports the resident microbial populations (20, 32). Indeed, judicious applications of soil organic matter can result in the suppression of diverse plant diseases in field and greenhouse systems (43, 47). However, complex interactions in the environment can significantly affect the suppressiveness of such amendments (6, 41). It is...
supposed that competition for nutrients is the primary driver of general suppression. In contrast, specific suppression is mediated by one or just a few microbial populations that antagonize resident pathogens (49). Production of antibiotics is considered a key feature of microbes associated with specific suppression (37, 38). Studies of suppressive soils have led to the identification of useful biological control strategies for suppressing plant pathogens. For example, culture-dependent (52) and culture-independent (54, 55) methods have been used to identify and isolate multiple microbial antagonists that can effectively suppress soilborne pathogens in field trials (34, 35). As a result, studies of soil microbial community structure are considered useful for developing innovative methods for pathogen and disease suppression (26).

Using concepts garnered from microbially based disease suppression in soils, we hypothesized that suppression of E. coli O157:H7 would be mediated by the predominant microorganisms present in the bedding in and around the cattle. The objectives of the current study were to determine (i) the degree to which biologically based suppression of E. coli O157:H7 occurred in bedding samples taken from different points on the farm and (ii) which bacteria present in such samples might contribute to the noted suppression. We focused on bacteria because previous studies had demonstrated that an overwhelming proportion of the microbial communities of manure were expected to be prokaryotic.

MATERIALS AND METHODS

Livestock bedding sources. Samples were taken on 18 August 2008, 10 November 2008, and 23 March 2009 (subsequently referred to as August, November, and March, respectively) from a dairy operation near Orrville, OH. At this operation, about 2,500 head of cattle were kept for milk production under free-stall housing conditions, where animals had free access to enter and leave resting areas in the barn that were lined at the bottom with a sand mix as bedding material. This dairy used a sand-manure separator (an auger 90 cm in diameter by 9.9 m long; McLanahan Corporation, Hollidaysburg, PA). Three times per week, a mix of fresh and recycled sand (1:1) was supplied as bedding material to the resting boxes with a mechanical distribution wagon. Through the action of the cows entering, exiting, and the stall, the sand was pushed from the front to the back end of the stall and eventually into the gutter, where it was mechanically collected and transferred to a washing facility for recycling. In this process, the material was moved by a separator auger from a collection pit into a temporary storage pile while it was being washed with water to separate the organic material from the sand. After it was air dried for 2 or more days in an open stockpile, the used sand was mixed with freshly purchased commercial clean sand and distributed in the livestock stalls to start the cycle anew. In this study, samples were collected from four sources within the recycling process of the livestock bedding: (i) fresh, consisting of recently applied bedding sand collected from the front of the resting stall (bedding 1); (ii) use, consisting of bedding from the rear of the resting stall (bedding 2); (iii) washed, consisting of used livestock bedding collected immediately after separation in the sand-manure separator (bedding 3); and (iv) recycled, consisting of washed bedding material rested for 2 or more days in a pile (bedding 4).

Samples (1,200 ml) were taken and placed in plastic bags for transport to the laboratory; beddings 1 and 2 were collected from eight stall locations (four in the August experiment) from opposite sides of the barn. Samples of bedding 3 were collected as far distant as possible in a circular pattern from around a pile of 1.5 m in height and 2.5 m in diameter 90 cm off the ground. Beddings 4 were collected from a pile 2.0 m in height and 5 m in diameter 90 cm off the ground. Samples were transported to the laboratory in ice coolers.

Chemical analysis of the bedding material. A portion of each bedding sample was submitted to the Service Testing and Research Laboratory (STAR lab) at the Ohio State Agricultural Research and Development Center (OARDC), Wooster, OH, for analysis of soil chemical parameters. The organic matter content was determined by the loss-on-ignition method (13), the pH was determined by the method by Thomas (48), nitrogen was quantified as described by Mulvaney (30), and carbon was quantified by the ISO 10694:1995(E) method (2).

Heat treatment and inoculation of bedding samples with E. coli O157:H7. After overnight storage in the laboratory, two 150-g portions of each of the samples were weighed into 250-ml Erlenmeyer flasks (250-ml beakers for the August experiment) and covered with aluminum foil. One set remained nonheated, and a second set was heated for 30 min at 80°C. For the latter, glass beakers with the contained bedding material were submerged in the preheated water of a 20-liter-capacity water bath and kept there for 30 min after a monitoring sample had reached the target temperature (experiments 1 and 2) or were kept in the water bath for 30 min total (experiment 3). This heat treatment was chosen because most bacteria should be severely reduced in number if they were not killed off at this temperature; such heat treatments had been used to disrupt the microbial communities of container substrates and suppressive soils (4, 52). All inoculations were done with a green fluorescent protein-labeled E. coli O157:H7 strain (American Type Culture Collection strain ATCC 43888). This transformation was previously demonstrated to be stable for at least 24 days when survival in fruit juices was monitored (16), and the nontoxigenic strain was expected to act similar to the toxigenic equivalent (21). After cooling of the heated bedding samples to room temperature, all samples were inoculated with suspensions of overnight cultures of this strain that had been spun down to remove the spent medium, resuspended in 1X phosphate-buffered saline (PBS) and adjusted to deliver concentrations of 10^7 CFU per gram of bedding material. This was determined spectrophotometrically at 0.16 to 0.35 optical density (OD) units/ml. The containers with the inoculated bedding samples were closed with their corresponding aluminum foil and incubated at room temperature (21°C) in the laboratory. Samples were taken after vigorous mixing with a spoon for enumeration of the CFU of E. coli O157:H7 and for DNA extraction on terminal restriction fragment length polymorphism (T-RFLP) analysis.

Enumeration of CFU of E. coli O157:H7. In all three experiments, samples were taken 1 day, 1 week, and 2 weeks after inoculation (experiment 1, at 1, 8, and 15 days postinoculation [dpi]; experiment 2, at 1, 7, and 15 dpi; and experiment 3, at 1, 10, and 17 dpi). Depending on the expected numbers of CFU of E. coli O157:H7, samples of 1 to 10 g were taken from the inoculated bedding sources and suspended in 20 to 50 ml of 1X PBS (8.00 g NaCl, 0.20 g KCl, 1.44 g Na2HPO4, and 0.24 g KH2PO4 adjusted to pH 7.4) by vortexing 4 times for 15 s each time, processing in a sonicator (Aquadson ultrasonic cleaner 75FT; VWR, West Chester, PA) for 1 min at 35 kHz, and vortexing at room temperature for 15 s. These suspensions were either plated directly onto the medium plates or entered into a 5-fold dilution series in 1X PBS in microtiter plates and then plated. The medium plates were LB medium (10 g Bacto tryptone, 5 g Bacto yeast extract, 5 g NaCl, and 1 liter double-distilled water adjusted to pH 7; 15 g agar was added and the medium was autoclaved for 20 min) amended, after it was cooled to 50°C, with ampicillin at 96 µg/ml and cycloheximide at 50 µg/ml on 10-cm-diameter agar plates.

After incubation at 37°C for 24 h, colonies were counted under UV light, and the terminal dilution factor and frequency of the green fluorescent colonies were recorded. The proper dilution factor of the test plates to obtain the number of CFU per gram of bedding material were calculated by a most-probable-number approach using the original terminal dilution factors. The terminal dilution factors for each sample source were converted to log-transformed data [log_{10}(CFU) per gram] by the proper formulas, considering the different dilution ratios, and the medians were presented in box plots; statistical groupings were derived from the analysis of the terminal dilution factors of the 5-fold dilution series.

DNA isolation. On the days of dilution plating, 0.25-g subsamples (0.25- to 0.35-g subsamples in experiment 1) of the incubated material were weighed into centrifuge tubes and frozen at −80°C for at least 24 h before DNA was extracted with a PowerSoil DNA extraction kit (MO BIO Laboratories, Carlsbad, CA). DNA extraction was done according to the manufacturer’s protocol, with two exceptions: first, centrifugation was at 9,000 × g (10,000 rpm) whenever 15- to 20-g g was suggested, and second, 450 µl was collected from each of the samples in the extraction tubes at the first collection step where the protocol suggested 400 to 500 µl to improve sample size uniformity. After extraction, DNA was either used immediately (being stored at 4°C between daily operations) or stored at −20°C.

DNA amplification and digestion and fragment analysis. The 16S rRNA genes in the DNA extracts of the bedding material were amplified with primer 8F (5′-AGAGTTTGTATCCTGCGGTA3′) labeled with WellsRED dye D4 (Sigma, Proligo, St. Louis, MO) and primer 1492B (5′-ACGGCTACCTGTAGACGATT-3′), on the basis of a previous description (49). A 25-µl reaction mixture with final concentrations of 1.8 mM MgCl2, 0.2 mM deoxynucleoside triphosphate mix, 0.8 µmol µl−1 each of primer 8F-D4 and primer 1492B, 0.04
mg µl⁻¹ of RNAse (Novagen, EMD Chemicals, Darmstadt, Germany), 1× PCR buffer of the GoTaq Flexi kit (Promega Co., Madison, WI), and 0.06 U µl⁻¹ GoTaq Flexi (Promega) in sterile water (Sigma, St. Louis, MO), including 2.5 µl of the DNA extract (1:20 dilution of the original DNA extract), was submitted to amplification.

Amplification reactions were conducted in a PTC-200 thermal cycler (Peltier thermal cycler; MJ Research Inc., Waltham, MA) with the following program: after an initial 5 min at 95°C, 28 cycles of 1 min at 94°C, 45 s at 54°C, and 60 s at 70°C and then 5 min at 70°C. The resulting amplification product was cooled to 4°C and digested either immediately or after it was frozen once at −20°C.

For restriction digestion, reaction mixtures of a total of 10 µl containing 0.3 µl of the enzyme MspI (10 U/µl), 0.5 µl of the corresponding buffer B (Promega), 3.5 µl of the PCR product, and 5.7 µl of sterile purified water were incubated for 4 h at 37°C and 25 min at 65°C and were stored initially at 10°C and later at 4°C.

For purification, according to a modified protocol of the Molecular and Cellular Imaging Center (MCIC), 10 µl of the digest was amended with 1 µl of a 3 M sodium acetate (pH 5.2) and 27.5 µl of 95% ethanol (cooled at −20°C), mixed, and incubated at −80°C for at least 10 min. After centrifugation at 6,130 × g in an SS700 swinging-bucket rotor (Allegra 25R centrifuge; Beckman Coulter, Fullerton, CA) for 15 min at 4°C, the pellet was rinsed twice with 70% ethanol chilled at −20°C. After each rinse and careful blotting on paper towels, the plates were spun at 6,130 × g for 2 min at 4°C. After the rinses, the plates were reversed in the centrifuge holders, spun at 180 × g for 1 min to remove excess rinsate, and then dried in a laminar-flow hood. The pellets were resuspended in 15 µl of sterile purified water. A 5-µl mixture (1:1) of the purified digest with sterile purified water was submitted for fragment size analysis at the MCIC. There, 0.1 µl of the sample was mixed with 0.5 µl 600-nucleotide (nt) size standard (CEQ DNA size standard kit 600) and 40 µl formamide solution. Samples were analyzed with a CEQ 8800 genetic analysis system (Beckman Coulter).

Fragment length data handling. Data from the fragment analysis obtained from MCIC were entered into CEQ8000 software and analyzed in the mode for amplified fragment length polymorphism analysis of the D4 signal with a dye mobility calibration and a size standard of 600 nt in a quartic model; the bin size was 1 nt. Fluorescence signals at intensities of ≤300 were excluded from the data to reduce background signal.

After export to a tabular processing program (Excel, Microsoft Office), the data were processed before statistical analysis, as follows. Binning of the terminal restriction fragments (TRFs) was first conducted. For TRFs of ≤300 nt in length, TRF size classes (bins) of ≤1 nt were combined, when several of the signals appeared in multiple bins under consideration. For TRFs of >300 nt, such combining was done for ≤2 nt. In a second step, bins with <4 signals across the entire data set were eliminated from consideration, as no significant differences would be attributable to such rare events. TRFs with 4 to 8 observations were kept if the majority of the fluorescence was associated with specific treatments and were eliminated if the signals were randomly scattered among treatments.

A tiered method of screening the data was used to identify fragments associated with E. coli O157:H7 suppression. In the first step, data were mined for differences between the fluorescence intensities of a specific TRF in nonheated versus heat-treated bedding samples. In the second step, signal strengths were interval plotted to allow comparison of the fluorescence of nontreated and heat-treated samples. For TRFs of 4 to 8 observations were kept if the majority of the fluorescence was associated with specific treatments and were eliminated if the signals were randomly scattered among treatments.

contribute to the suppression of *E. coli* O157:H7 in sand bedding samples.

The median numbers of CFU of *E. coli* O157:H7 declined in all contexts (nonheated or heated) over time (Fig. 1A to C), suggesting that inhibitory factors in addition to the microbial suppressiveness were not destroyed by the heat treatments. The dynamics of the decay curves varied somewhat from experiment to experiment. However, initial levels of suppressiveness (i.e., decay during the first 24 h) were most dramatic in the recycled bedding samples (sample 4) in all three experiments.

![FIG. 1. Suppression of *E. coli* O157:H7 in four livestock bedding sources. Bedding samples were acquired on August 2008 (n = 4) (A), November 2008 (n = 8) (B), and March 2009 (n = 8) (C). Sources were as follows: fresh, front of the cow box; in use, back of the cow box; washed, used material from the pile following use of the sand-manure separator; and recycled, rested (≥2 days) pile of washed bedding material. Heat indicates that fresh livestock bedding samples were left either nonheated (n) or heated (h) at 80°C for 30 min to kill off the majority of endogenous microbes before they were subsequently cooled to room temperature. *E. coli* O157:H7 was then added at 10⁷ CFU g⁻¹ to all samples and incubated at room temperature. The numbers of CFU of *E. coli* O157:H7 were measured by dilution plating on LB medium amended with ampicillin (50 μg ml⁻¹) and cycloheximide (96 μg ml⁻¹) at 1 dpi or at 7, 10, and 15 dpi. Within each time point, the values for bars indexed with the same letter were not significantly different at *P* equal to 0.05 when the terminal dilution factors of a 5-fold dilution series were analyzed with Mood’s median test. The log-transformed \([\log_{10}(x)]\) numbers of CFU of *E. coli* O157:H7 are presented.](http://aem.asm.org/...)
Such differences were significant ($P < 0.05$) in two of the three experiments.

In the August experiment (Fig. 1A) at 1 dpi, the numbers of CFU of E. coli O157:H7 were lower for all nonheated bedding samples than the equivalent heated samples; these differences were statistically significant for the source fresh only. Within the nonheated or heated sample group, the numbers of CFU were similar for the different sources. At 15 dpi, most of the CFU of E. coli O157:H7 had declined; more E. coli O157:H7 cells survived only in samples from the heated fresh and recycled sources than in the nonheated equivalents; within the nonheated or heated samples, the numbers of CFU were similar.

In the November experiment (Fig. 1B) at 1 dpi, the numerical values for the numbers of CFU of E. coli O157:H7 were lower for all nonheated bedding samples than the heated equivalents; these differences were statistically significant for the fresh and recycled bedding. Recycled bedding had the fewest CFU of all nonheated samples, whereas the numbers of CFU were similar for all heated samples. At 7 dpi, the numbers of CFU of the nonheated samples were lower than those of the heated ones, except for the in-use source; CFU were not detected in nonheated samples from the washed source, and this source had the lowest numbers of CFU of all nonheated bedding samples.

In the March experiment (Fig. 1C) at 1 dpi, there were significantly fewer CFU of E. coli O157:H7 in all nonheated bedding samples than in the heated equivalents; the numbers of CFU for all of the latter samples were similar. The recycled bedding had fewer CFU than the nonheated in-use and washed samples. At 10 dpi, the numbers of CFU in all nonheated samples were lower than the numbers in the heated ones; the numbers of CFU for the nonheated washed and recycled samples were lower than the numbers for the fresh material, whereas the number of CFU in the in-use material was intermediate.

**T-RFLP analyses and association of heat-sensitive bacterial TRFs with suppressiveness.** In order to determine what components of the bacterial communities present in the bedding samples might contribute to the patterns of observed suppressiveness, we conducted T-RFLP analyses of amplified 16S rRNA gene sequences from all samples. Interval plotting and regression analyses of the relative abundance of different TRFs were conducted to identify candidate TRFs that were more abundant in more suppressive sample pairings in each experiment. For example, in the nonheated versus heated sample pairings of each bedding source, 31 of the 100 total TRFs in the August experiment (see Table S1 in the supplemental material), 67 of the 149 total TRFs in the November experiment (see Table S2 in the supplemental material), and 78 of the 131 total TRFs in the March experiment (see Table S3 in the supplemental material) were tentatively identified to differ in abundance. Because the two mathematical approaches identified different subsets of TRFs of interest, we focused our efforts on identifying those TRFs repeatedly observed to differ using both approaches (boldface values in Tables S1 to S3 in the supplemental material). Thus, while there was a high degree of sample-to-sample variation in the profiles, some TRFs were repeatedly observed to occur in comparisons of more suppressive sample pairings than less suppressive sample pairings in individual experiments.

In the August experiment (see Table S1 in the supplemental material) at dpi 1, a total of 22 TRFs had greater fluorescence in the nonheated than the heated portions of the bedding sources; 27 TRFs had a negative relationship of the numbers of CFU of E. coli O157:H7 over fluorescence, but only 4 TRFs in fresh bedding fulfilled both selection requirements simultaneously. At 15 dpi, there were 25 TRFs with higher fluorescence in nonheated than heated soil, and 51 exhibited a negative relationship with the numbers of CFU of E. coli O157:H7; TRFs M130, M139, and M156 fulfilled both selection criteria and occurred in fresh and in-use bedding materials. Additional TRFs fulfilled both selection criteria but occurred only in one source.

In the November experiment (see Table S2 in the supplemental material) at 1 dpi, the numbers of TRFs of the candidates were higher in the nonheated samples 59 times, and 35 negative regressions with the numbers of CFU of E. coli O157:H7 were detected; but TRFs fulfilled both selection criteria only 12 times when the information for in-use bedding, washed, and recycled bedding is summarized; none were detected in fresh bedding. At 15 dpi, the numbers of TRFs of the candidates were higher in nonheated portions than heated portions 126 times, and a negative regression of the TRF fluorescence with the numbers of CFU of E. coli O157:H7 was detected 84 times. TRFs fulfilled both parameters 65 times. Several TRFs occurred in different sources at the same sampling time; some occurred repeatedly within one sampling time and at both samplings.

In the March experiment (see Table S3 in the supplemental material) at dpi 1, fluorescence was stronger in the nonheated than in the heated equivalents 102 times and there was a negative regression of the numbers of CFU and TRF fluorescence 109 times. TRF fulfilled both requirements a total of 50 times. At dpi 10, the fluorescence was higher in nonheated than in heated equivalents 86 times; there was a negative regression 83 times. Both parameters were fulfilled 21 times.

Identification of bacterial TRFs enriched in unheated bedding samples with the highest initial suppressiveness. A similar screening approach was used to identify TRFs that were more abundant in the unheated bedding samples which displayed the greatest initial decay of inoculated E. coli O157:H7 populations (Fig. 1A to C). Comparisons of the T-RFLP profiles of the washed and/or recycled bedding to those of the other samples were conducted for the two experiments where significant differences in suppressiveness were noted, i.e., in the November experiment (see Table S4 in the supplemental material) and the March experiment (see Table S5 in the supplemental material).

At dpi 1, fluorescence was stronger in the nonheated recycled bedding than in the nonheated fresh, in-use, or washed material 29 times; there were negative regressions 27 times (see Table S4 in the supplemental material). Four to six TRFs that fulfilled both requirements were detected. At dpi 7, TRFs of nonheated washed samples had higher fluorescence than nonheated fresh, in-use, or recycled material 32 times; no regression analysis could be conducted for the washed samples because no E. coli O157:H7 was detected. TRF M118 occurred...

a Livestock bedding samples from four distinct sources (fresh, in use, washed, recycled) were split into one nonheated (NH) and one heated (HT) sample, TRFs were recorded for higher fluorescence in nonheated than heat-treated samples (parameter A) and negative regression of the surviving numbers of CFU of E. coli O157:H7 over fluorescence strength or between nonheated samples of different levels of suppressiveness (parameter B). b TRFs of <300 nt were at an accuracy of ±1 nt; TRFs of >300 nt were binned at ±2 nt. c Frequency of occurrence of TRFs with both parameters A and B fulfilled in a total of 37 contexts. d Sampling times: early, 1 dpi; late, 15 dpi (experiment 1), 7 dpi (experiment 2), or 10 dpi (experiment 3). The numbers in the table indicate the experiment(s) in which the TRFs were detected. e These comparisons among nonheated bedding samples 1 through 4 were conducted only in experiments 2 and 3; in experiment 1, the samples from the recycled source did not have significantly more CFU than those from the fresh source. f TRFs of >300 nt were binned at ±2 nt.

In all these comparisons, TRF M299 and TRF M508 occurred at 1 dpi, and TRF M202 occurred only at 7 dpi.

When samples from the recycled source were compared to those from the fresh, in-use, and washed sources, fluorescence was higher in recycled samples 17 times and the regression was negative 10 times. Both parameters were fulfilled 14 times (see Table S5 in the supplemental material). The washed samples had more fluorescent TRFs five times and a negative regression six times, but no TRFs fulfilled both requirements. Similarly, recycled samples had more fluorescence than fresh or in-use samples five times, but none had a negative regression.

Identification of bacterial populations most commonly associated with suppressiveness to E. coli O157:H7. In the total of 37 comparisons of the August, November, and March experiments outlined above, elevated levels of TRF M299 occurred in 9 comparisons spread over different experiments and sampling times (Table 2). Similarly, TRF M118 was elevated eight times. TRF M142 occurred a total of seven times at various sampling times in all three experiments. TRF M89 and TRF M156 occurred six times: the former in the November and March experiments and the latter in all three experiments at late or early times. TRF M96, TRF M99, TRF M202, TRF M488, TRF M492, and TRF M508 all occurred in five contexts, typically restricted to two of the three experiments.

In order to identify the bacteria giving rise to these TRFs, we size selected and sequenced clones amplified from the original samples. The sequences were trimmed from the 8F primer to the MspI site and subjected to BLAST analysis (1). Small to medium-sized TRFs were more often successfully cloned than larger TRFs. To assess the novelty of the bacterial species identified, we evaluated the percent identity across the full length of the fragment for both the best overall match and the best published match with a named genus or species designation (Table 3). The smaller TRFs belong to a variety of genera in the diverse Bacteroidetes (previously known as the Cytophaga-Flexibacter-Bacteroidetes group), which have 99 to 100% identity to uncultured bacteria from agricultural environments. The medium-sized TRFs were mainly associated with two bacterial groups, the gammaproteobacteria and the firmicutes. The larger TRFs were associated with the gammaproteobacteria and betaproteobacteria. No clones corresponding to either TRF M118 or M202 were identified.

DISCUSSION

Here we present the first evidence that the suppression of E. coli O157:H7 in the environment is mediated by heat-sensitive microorganisms (Fig. 1). Other work has established the use of such heat treatments for the determination of biologically based pathogen suppressiveness (42, 51, 52, 53). LeJeune and Kaufman (22) tested the ability of E. coli O157:H7 to survive in sawdust and sand bedding materials collected from dairy operations. The authors showed that E. coli O157:H7 survived at higher densities and for longer periods of time in used sawdust bedding than in used sand bedding. No mechanism for that apparent suppression was elucidated; however, they posited that the differences in survival were influenced by the presence of toxic substances and the lack of water, organic matter, and/or nutrients in sand bedding. While physical and chemical properties of the matrices might affect the survival of the inoculated pathogen, we found no associations between the survival of E. coli O157:H7 and the sample pH or the amount of carbon or nitrogen in this study. Effects of soil moisture differences, though not recorded in detail, were also discounted as a possible source of variable survival because water potential was previously demonstrated to have limited effects on survival of E. coli O157:H7 (40). These findings further expand the collective understanding of pathogen population dynamics on the farm by illustrating that zoonotic bacterial pathogens can be suppressed in situ by other bacterial populations. It has long been known that diverse oomycete, fungal, and...

Suppression of E. coli O157:H7 in cattle manure by bacterial communities (Table 3)

The validity of this TRF-based approach was further supported by the initial identification (8) and subsequent recovery (7) of novel bacterial groups belonging to the Genera incertae associated with the suppression of plant pathogens. Some of the TRFs identified here may also come from novel species, on the basis of the low sequence levels of identity of some TRFs to the database sequences (e.g., M488 and M510; Table 3). Similar community profiling approaches have also been used successfully to first identify and subsequently recover microbial antagonists of plant pathogenic nematodes (9, 54, 55). Still, the ultimate proof that the 11 TRFs mark bacteria that actually suppress E. coli O157:H7 in situ will depend on culturing representative bacteria harboring those sequences. Unfortunately, the dairy farm from which the samples were taken in this study is no longer operational (a victim of the recent economic crisis), so sampling for recovery from the same materials is not possible. However, it seems likely that similar, if not clonal, strains exist on other farms, given the cosmopolitan nature of most bacterial species. Subsequent efforts to recover and phenotypically characterize bacteria harboring the identified TRF tags are under way and could lead to the development of an inoculant-based strategy to suppress E. coli O157:H7, in a manner analogous to applied biocontrol in the field of plant pathology.

Previously, Benítez et al. (8) used two separate statistical approaches to identify candidate TRFs associated with (plant) pathogen suppression. Here, we improved on that screening approach by using an additional statistical criterion (regression analysis) to further restrict the number of candidate TRFs considered to be associated with suppression, thereby reducing the potential number of false-positive associations of phenomenological significance. Remarkably, the more restrictive se-
lection criteria applied in this study resulted in an even greater number of candidate TRFs than that previous study examining root disease suppression (i.e., 11 candidates here [Table 2] versus 8 previously [8]). The significance of this is not clear, but it might indicate that bacterium-mediated suppression of strain O157:H7 is less specific than the general suppressiveness to soilborne plant pathogens noted in the earlier study. Such a conclusion is further supported by the observation that many more TRFs were associated with E. coli suppression at different sampling times (Table 2), but only 11 TRFs were observed repeatedly in different samplings (Table 2). Also, the results presented do not preclude other organisms from being involved in suppressiveness.

Because they were found in most all of the samples to various degrees, it is likely that the bacteria giving rise to the 11 noted TRFs were likely present in the feces of the cattle themselves. However, because the greatest suppressiveness was observed in the recycled sand pile (bedding source 4, 1 dpi; Fig. 1), such populations are probably subdominant members of the community until some curing of the bedding takes place, allowing them to become more abundant and/or more active. Interestingly, changes in the relative abundance of specific antagonists, such as phd-positive Pseudomonas species, have also been associated with the suppression of some plant pathogens (28, 29).

The identified subset of 11 TRFs appears to have been amplified from a variety of bacterial groups (Table 3). These include the diverse Cytophaga-Flexibacter-Bacteroidetes group, the well-known Gammaproteobacteria, and the primarily Gram-positive, spore-forming Firmicutes. Although some 16S rRNA TRF sequences showed greater than 99% identity to sequences in the database, there were some sequences whose best match showed less than 90% identity across the length of the TRF. In these cases lower sequence identity to database entries, we may have found markers for previously unidentified species of bacteria that are particularly suppressive to E. coli O157:H7 in situ. This hypothesis is supported by previous work where exploitation of similar correlations (8) led to the marker-assisted recovery of two bacterial species that displayed the predicted function of suppressiveness to the plant pathogens present in the tested soils (7).

The ecology of E. coli O157:H7 in the farm environment impacts the prevalence of O157:H7 on the farm and beyond. Franz and van Bruggen (15) recently reviewed the ecology of O157:H7 in the farm environment, the contribution of the farm environment to E. coli O157:H7 persistence is effectively reduced and the risk of food-borne contamination is minimized.
