Accidental selection and intentional restoration of sporulation-deficient
mutants of Bacillus anthracis

Running title: “Loss of sporulation in Bacillus anthracis”

We demonstrate the frequent accidental enrichment of spontaneous sporulation-deficient mutants of *Bacillus anthracis* on solid medium and identify contributing factors. Mutations in *spo0A*, encoding the master regulator of sporulation initiation, were found in 38 of 53 mutants. Transductions using bacteriophage CP51 propagated on sporogenic bacteria allowed restoration of sporulation phenotypes.
Bacillus anthracis is an endospore-forming bacterium and the etiological agent of anthrax. Bacillus spores are formed under conditions of high bacterial density or nutrient limitation; they are metabolically inert and resistant to unfavorable conditions such as extreme temperatures, pH, and desiccation (1). Spores can reside in the soil for many years until inhaled by grazing animals, whereupon germination and vegetative growth is initiated, accompanied by production of toxins and the antiphagocytic capsule, ultimately leading to anthrax disease and death (1).

Sporulation and germination in Bacillus are complex processes requiring the orchestrated action of many genes. Sporulation transcription factor Spo0A is a DNA-binding protein and master regulator for entry into sporulation; it controls expression of more than 120 genes directly (17), and its activity influences expression of approximately 12% of the entire genome (4). Spo0A belongs to the family of bacterial response regulators (8), and activated Spo0A binds to a 12-bp consensus sequence located within promoter sequences (17,28), thereby activating or repressing downstream located genes (18,25). Due to its pivotal role, mutations within Spo0A leading to inactivity result in complete loss of sporulation (7).

Bacteria constantly experience spontaneous mutation, which has been found to occur at $10^{-7}$ to $10^{-9}$ per base pair per generation (12). The observation that asporogenic mutants quickly overtake a continuous culture has been made in several spore-forming organisms, including Bacillus sphaericus (9), Bacillus thuringiensis (22), and Bacillus subtilis (15). Spontaneous Bacillus mutants defective in their ability to sporulate are useful tools to identify and characterize the function of genes involved in sporulation (2,5,7,24). However, accidental and/or unrecognized selection of such mutants is disadvantageous, especially during routine lab passage of strains and, e.g., generation of targeted genetic deletions, since many such mutants are intended to be used in spore challenge of animals to test virulence. We have noticed that this
selection occurs frequently in different strains of *B. anthracis* (unpublished). This work aimed to characterize asporogenic *B. anthracis* mutants, to identify factors influencing their selection, and to find methods for reverting accidentally selected mutants to a sporogenic phenotype.

For our studies, we used *B. anthracis* Sterne, an attenuated strain harboring virulence plasmid pXO1, but devoid of plasmid pXO2 (10). We observed that after a 2-day incubation period at 37°C, *B. anthracis* often exhibit two distinct colony phenotypes on LB agar plates, with the majority of colonies being flat and white in color, but a small percentage (< 1%) being larger with a translucent appearance. Microscopic analysis in combination with the killing of vegetative bacteria by heat-treatment (65°C for 30 min in water) showed that the larger colonies harbored asporogenic bacteria, thereby allowing an easy visual identification of such mutants on LB agar.

To identify factors favoring enrichment of asporogenic mutants, we compared three conditions: (A) age of colonies, (B) number of passages, and (C) influence of media. For (A), we generated an LB master plate by plating a dilution of a single sporogenic *B. anthracis* colony and each day picked different colonies from the master plate, diluting them and plating onto new LB plates. Phenotypic analysis of about 1000 colonies showed an increase in the percentage of asporogenic bacteria in correlation with the age of the master plates (Fig. 1A). Past day 9, the frequency of asporogenic bacteria decreased, presumably representing lysis of sporulation-deficient *B. anthracis* mutants present on the master plate. For evaluation of (B) and (C), sporulating colonies (n=100) were serially passaged on two different solid media. Fig. 1B shows that on LB plates, the number of colonies consisting of asporogenic bacteria increased greatly with increasing number of passages. In contrast, on BHI plates, this percentage never exceeded 10%, indicating BHI to be a better medium for avoiding enrichment of sporulation mutants. However, we found that mutants are visually not as easily identifiable on these plates as on LB agar; only
after complete lysis of asporogenic bacteria had occurred on BHI agar was it possible to visually identify such mutants therefore exacerbating the difficulty of early recognition and counter selection.

In *B. cereus*, sporulation stage 0 mutants are enriched under nitrogen-limiting growth conditions, and several mutants were found to harbor mutations in Spo0A (16,19). To investigate the possible role of this regulator, we sequenced *spo0A* in 53 asporogenic mutants using primers Sposeq1 (ttgtcgaacatcttagcc) and Sposeq2 (tcaagaatgaagctttatgaaaa). Supplementary Table 1 lists the 38 strains found to have mutations in *spo0A*; the majority (n=21) displayed missense mutations that may not affect function of Spo0A. However, the DNA binding motif of Spo0A is located between amino acid 193 and 224 (28), and 13 of the mutants harbored different mutations in this region (Fig. 2A), most of which could be expected to lead to loss of regulatory function. Other mutants (n=16) harbored nonsense mutations, insertions, or deletions, thus clearly affecting functionality of Spo0A. In one of the analyzed mutants (LL44), which was derived in a separate experiment from *B. anthracis* UM44-1C9 (13), illegitimate recombination occurred, an event that takes place between short direct repeats (3,27). Consequently, a 2116-bp fragment in the *spo0A* region starting at a 10-bp direct repeat present in the coding region of *spo0A* and ending at an identical repeat within the downstream gene was deleted (Fig. 2B), as determined by sequencing with primers Sposeq1 and Sposeq5 (ttcataaatgcaaatgcctca). Furthermore, we found that a 7-bp direct repeat (TTCATAT) within the coding region of *spo0A* was altered in 2 mutants, either by deletion (SPO105) or duplication (SPO112), both of which disrupt the reading frame (Fig. 2C). These mutations are likely caused by replication errors, or slipped-strand mispairing (SSM) often found to occur at tandem repeats (14). Interestingly, we found the strain harboring the 7-bp duplication to spontaneously revert to
wildtype (data not shown), thereby restoring Spo0A function. This offers a strategy in which genetic manipulations such as multiple gene knockouts could be performed in this mutant strain, since the pre-existing spo0A mutation removes the selective pressure that would enrich for other spontaneous mutations in sporulation genes. After all the intended genetic changes are introduced, the final strain could be reverted to the wildtype spo0A genotype.

For B. subtilis, it was reported that mutations in some sporulation genes such as spo0A result in higher intracellular fluxes of metabolites and increased biomass yield (5). We evaluated the growth characteristics of two of the B. anthracis asporogenic mutants, one harboring an insertion (SPO7) and the other a deletion (SPO18). While the wildtype had a significantly (p < 0.001, ANOVA and Tukey’s post-test) prolonged lag phase, mutants SPO7 and SPO18 quickly entered exponential growth phase (Table 1); however, growth rate differences during logarithmic growth proved to be insignificant (p = 0.46, ANOVA with Tukey’s post-test) (Table 1). These results show that loss of sporulation in B. anthracis can lead to a shortened lag phase but does not give bacteria an advantage during exponential growth.

Generating genetic knockout mutants is a time-consuming process, even though improved and faster mutagenesis approaches have been described for B. anthracis (11,20,21). If a final deletion mutant proves to be asporogenic, it must be considered that the sporulation defect is a secondary mutation unrelated to the gene under study. To overcome this problem, we sought a faster approach allowing the restoration of sporulation and attempted to use phage transduction to introduce DNA from sporogenic into asporogenic mutants, ultimately reverting asporogenic mutants to wildtype phenotype. We selected two mutants having spo0A mutations known to result in inactivity (SPO18 and SPO128) and one with a missense mutation that could leave Spo0A functioning (SPO91) (Suppl. Table 1). For transductions, a heat-sensitive derivative of
Bacillus phage CP51 (26), isolated from *B. cereus* 569 (CP51+) grown in BHI (0.5% glycerol) at 30°C for 15 h, was first propagated in sporulation-competent *B. anthracis* by mixing 1 ml phage suspension with 1 ml vegetative *B. anthracis* (grown for 5 h in LB containing 0.5% glycerol). Phage assay (PA) agar (6) was added to the phage/bacterial mixture, which was then overlaid onto NBY plates (6) containing 0.5% glycerol, and incubated at 30°C for 30 h. Phages from entire plates were harvested in 5 ml PA broth, sterile filtered (0.45 µm, Millipore), and used for transductions of asporogenic mutants SPO18 and SPO128 by incubating 1 ml of phage suspension with 1 ml of asporogenic, vegetative bacteria grown as described above. Phage/bacterial mixtures were incubated for 1 h at 37°C (which prevents phage replication and cell lysis), and then grown on sporulation plates (23) at 37°C under lack of selective pressure for 3-5 days, and subsequently heat-treated to eliminate non-sporulating bacteria prior to plating on LB agar. Each transduction experiment yielded several viable (i.e., sporulation-competent) colonies, which were confirmed microscopically, and no spontaneous, sporogenic revertants were obtained in parallel control experiments. Subsequent sequencing of the sporulation-competent transductants revealed that the mutations present in SPO7 and SPO18 were eliminated after phage transduction. In contrast, the missense mutation present in SPO91 (R211C) remained, indicating that it did not alter Spo0A function since the transductants readily formed spores. Therefore, mutation of a different gene was responsible for loss of sporulation in mutant SPO91, and it was this unidentified mutation that was corrected by transduction. This result shows that for reversion of asporogenic mutants accidentally enriched in the laboratory, phage transductions can be a powerful method for restoring sporulation caused by mutations in an unknown location, thereby allowing the rescue of an otherwise desirable strain.
Taken together, this work describes an easy method to detect asporogenic mutants on agar plates, describes media and lab techniques that may help to prevent accidental selection, and lastly provides an approach to restore the sporogenic phenotype in accidently selected mutants. Although under laboratory conditions the loss of sporulation and mutation of *spo0A* was a frequent event, it remains unknown how often and whether this phenomenon occurs in nature.

Figure 1: Influence of number of passages, media, and age of colonies on frequency of asporogenic mutants. (A) Percentage of sporulation-deficient mutants derived from colonies of different age. (B) Percentage of asporogenic mutants retrieved from subsequent passages of 100 individual colonies.

Figure 2: Schematic overview of mapped spo0A mutations caused by illegitimate recombination and replication errors. (A) Amino acid sequence alignment of the helix-turn-helix motif of sporulation mutants harboring missense mutations in this region. The first 6 amino acid substitutions were each found in the two isolates listed at the left. (B) A region of 2116 bp between two 10-bp direct repeats present in spo0A and GBAA4321 in the chromosome of wildtype B. anthracis was deleted in strain LL44, eliminating the C-terminus of Spo0A and the N-terminus of the adjacent protein. (C) A 7-bp direct repeat within spo0A was deleted in strain SPO105, whereas the same repeat was duplicated in mutant SPO112 (underlined); both mutations led to loss of Spo0A activity.

Figure 3: Growth curves of wildtype strain 34F2 in comparison to two asporogenic mutants. Bacteria were inoculated in LB from an overnight culture and grown over a period of 7 h.
