Abstract

Currently, nitritation-anammox (anaerobic ammonium oxidation) bioreactors are designed to treat wastewaters with high ammonium concentration at mesophilic temperatures (25 - 40 °C). The implementation of this technology at ambient temperatures for nitrogen removal from municipal wastewater following carbon removal could lead to more sustainable technology with energy and cost savings. However the application of nitritation-anammox bioreactors at low temperature (characteristic of municipal wastewaters expect tropical and subtropical regions) is not yet explored. To this end, a laboratory-scale (5 l) nitritation-anammox sequencing batch reactor was adapted to 12 °C in 10 days and operated for more than 300 days to investigate the feasibility of nitrogen removal from synthetic pre-treated municipal wastewater by the combination of aerobic ammonium-oxidizing bacteria (AOB) and anammox. The activities of both anammox and AOB were high enough to remove more than 90 % of the supplied nitrogen. Multiple aspects, including the presence and activity of anammox, AOB, and aerobic nitrite oxidizers (NOB) and nitrous oxide (N₂O) emission were monitored to evaluate the stability of the bioreactor at 12 °C. There was no nitrite accumulation throughout the operational period indicating that anammox bacteria were active at 12 °C and that AOB and anammox bacteria outcompeted NOB. Moreover, our results showed that sludge from wastewater treatment plants designed for treating high ammonium load wastewaters could be used as seeding sludge for wastewater treatment plants aimed at treating municipal wastewater that has low temperature and low ammonium concentrations.
Introduction

Nitrogen removal from wastewater treatment is necessary because of the significant adverse environmental impact of ammonia/ammonium on the receiving bodies, such as eutrophication and toxicity to aquatic life. Generally, carbonaceous waste is removed in the first stage of wastewater treatment, which is followed by nitrogen removal systems. Conventionally, the removal of nitrogen (ammonium) is accomplished by the combination of nitrification and denitrification processes. Both of these are energy consuming and are associated with high costs. Moreover, these processes have an additional environmental impact, due to high biomass production and greenhouse gas (CO$_2$, N$_2$O, etc) emission, which promote global warming.

Anaerobic ammonium-oxidizing (anammox) bacteria convert ammonium and nitrite directly to dinitrogen gas (N$_2$) under anoxic conditions. Since they were first detected in a denitrifying pilot plant by Mulder et al. in 1995 (1), anammox bacteria have been found in various oxygen-limited natural (2-4) and manmade ecosystems. The application of the anammox process in wastewater treatment results in significant energy reduction (60%) and greenhouse gas emission (90%) compared to traditional biological nitrogen removal processes (5-7). In full-scale nitritation-anammox wastewater treatment plants, AOB convert approximately half of the supplied ammonium to nitrite under O$_2$ limitation, and in turn, nitrite, together with the remaining ammonium is converted to N$_2$ by anammox bacteria (8, 9). These systems are already applied for the treatment of warm and high strength wastewaters such as digester effluents and anaerobically treated industrial effluents (10, 11).
A more sustainable municipal wastewater treatment could be achieved with a first step where available organic carbonaceous compounds are concentrated and converted to (CH₄) in an anaerobic digester (6). The remaining wastewater would only have ammonium left as the major pollutant and a nitritation-anammox process could be applied for nitrogen removal. However, municipal wastewater has a lower temperature (~ 10-15 °C, apart from tropical and sub-tropical regions) and relatively low ammonium concentration (12). This could lead to lower specific activities and growth rates for both anammox bacteria and AOB. Indeed, it was reported that the activity of anammox bacteria and AOB both decreased at 15 – 20 °C (13, 14) and that partial nitrification was difficult to achieve in winter because of the varying temperature of municipal wastewater (15). Nevertheless, several studies showed that nitrogen removal at lower temperature by anammox process could work (14, 16, 17); still, in none of these studies it was possible to maintain a stable anammox-AOB culture (nitritation-anammox) at temperatures lower than 20 °C. On the other hand, in natural ecosystems such as Northern European soils and marine sediments, anammox bacteria thrive under much colder temperatures and very low ammonium concentrations (μM range) (18, 19). Therefore, it should be possible to adapt a nitritation-anammox bioreactor to low ammonium concentrations to treat cold municipal wastewater using appropriate strategies.

To this end, a laboratory-scale (5 l) sequencing batch reactor (SBR) was inoculated with anammox biomass from an SBR operating at 30 °C. Oxygen was supplied gradually to allow the growth of AOB. The enriched nitritation-anammox biomass was
adapted to 12 °C. Synthetic wastewater simulating pretreated municipal wastewater was used as influent for the bioreactor. Activities of anammox, AOB and NOB were monitored by offline batch tests and the microbial community composition was investigated by molecular analyses including Fluorescence in situ hybridization (FISH) and clone libraries. The responses of specific activity of each functional community to temperature change and low ammonium concentrations were discussed.

### Materials and Methods

#### Reactor setup and operation

Two sequencing batch reactors (SBR, working volume 5 l) were used for the cultivation of anaerobic ammonium oxidizing bacteria (anammox) and nitritation-anammox biomass. A previously described anammox enrichment culture (20) was used to grow anammox biomass at different temperatures as follows. The anammox SBR was stirred at 200 rpm with a six bladed turbine stirrer. Each cycle consisted of 11 h of filling, 20 min of biomass settling and 40 min of drawing of the liquid. During each filling period, 1 l of mineral medium (21) containing 630 mg-N/l (45 mM) nitrite and ammonium were supplied to the anammox SBR. To maintain anoxic conditions, the reactor and the medium vessel were flushed continuously with Ar/CO2 (95/5%, 10 ml•min-1). CO2 present in the supplied gas and bicarbonate in the mineral medium was sufficient to buffer the solution and keep the pH in the reactor at ~7.3. The temperature of the reactor was maintained at 30 °C with a water bath. The temperature of the anammox SBR was decreased from 30 °C stepwise (5 °C steps) in 2 months to 15 °C. At each step, activity
tests were performed to determine the anammox activity as described below (activity
tests section).

When the anammox SBR described above was operated at 30 °C, one liter of this
culture (70-80 % enriched) was used as seed sludge to inoculate another SBR to enrich
nitritation-anammox biomass as follows. At the time of the inoculation the temperature
was decreased in one step from 30 °C to 25 °C. The nitritation-anammox SBR was
operated as described above with respect to SBR cycle, pH and anoxia. During each
filling period of the SBR cycle, 1 l of mineral medium (21) containing 420 mg-N/l (30
mM) nitrite and 588 mg-N/l (42 mM) ammonium were supplied for 93 days. Oxygen
(7.54 mg/d) was introduced to the reactor after two weeks of the inoculation to facilitate
the growth of AOB. To mimic municipal wastewater, ammonium and nitrite
concentrations were gradually decreased after day 94. The final concentration of
ammonium and nitrite in the influent were 70 mg-N/l (5 mM, Day 191) and 0 mg-N/l
(Day 119), respectively (Figure 1). Between days 125 and 136, the temperature of the
reactor was stepwise decreased to 12 °C (Figure 1). Biomass (1.5 ml) was collected
every two days for DNA extraction and every week for FISH analysis. When the system
was operated at 12 °C, over a period of 15 days (at days 330, 338 and 345), triplicate
gas samples (100 µl) were taken for N₂O measurements from both SBRs.

**Activity tests**

Specific activity of each functional community (Anammox, AOB and NOB) was tested
at days 13, 113, 137 and 268 that represent different operational stages (different
oxygen supply and temperature). For anammox activity tests, 10 ml biomass was taken
directly from the anammox SBR and the nitritation-anammox SBR. The samples were transferred to separate 30 ml serum bottles. After the addition of 1 - 2 mM (14 – 28 mg-N) nitrite and ammonium and adjusting the pH to 7.3, the bottles were capped with butyl rubber stoppers and sealed with aluminum crimp caps. The sealed bottles were then made anoxic by alternatively applying vacuum and supplying Ar/CO2 (95/5%) at least 7 times. The bottles were incubated in shaking incubators (200 rpm) at 10 - 50 °C with 5 °C increments. Liquid samples (0.5 ml) were taken every 20 to 60 minutes (depending on actual activity) for ammonium and nitrite measurements.

For AOB and NOB activity tests, 10 ml biomass from the nitritation-anammox SBR was transferred to a 50 ml Erlenmeyer flask under atmospheric conditions, biomass used for NOB activity test was first washed 3 times with HEPES buffer (4-(2-hydroxyethyl)-1-piperazineethane- sulfonic acid, 20 mM, pH 7.4) to remove all ammonium. Incubation and sampling procedures were same as the anammox activity tests.

**Analytical Methods**

Collected liquid samples were centrifuged (5 min, 10,000×g) and the supernatants were kept at −20 °C until further analyses. Ammonium, nitrite and nitrate were measured colorimetrically as previously described (22). Protein concentrations were measured using Biuret method as previously described (23). N₂O was measured with an Agilent 6890 Series GC (Agilent Technologies, USA) equipped with a Porapack Q column and an electron capture detector (ECD).

**Fluorescence in situ hybridization (FISH)**
Fluorescence in situ hybridization (FISH) was performed on the nitritation-anammox SBR as described previously (24) with probes specific for *Kuenenia* and *Brocadia*-like anammox bacteria [AMX820 (25)], *Kuenenia stuttgartiensis* [KST1273 (24)], AOB [NEU653 (26)], NOB [NTSPA0712 (27)] and [NIT1035 (28)]. DAPI (4',6-diamidino-2-phenylindole) was used to stain the whole community DNA.

**DNA extraction, PCR amplification, cloning and phylogenetic analyses**

Genomic DNA was extracted from 1 ml of centrifuged sample from the nitritation-anammox SBR, as described previously (29) and was stored at -20 °C until further analyses. DNA concentrations were determined by the NanoDrop 1100 spectrophotometer (Thermo Scientific, USA).

The 16S rRNA gene of anammox bacteria was amplified by PCR using the primer combination pla46F (28) and 1529R (30). For quantitative PCR, primer combination hzsA526F/hzsA1829R (31) and amoA-1F/amoA-2R (32) were used for anammox bacteria and AOB, respectively using the MyiQ™ Single-Color Real-Time PCR Detection System (BIO-RAD, USA). Each quantitative PCR reaction was performed in triplicate. To construct standard curves, plasmids containing the target gene were quantified using a NanoDrop 1100 spectrophotometer, then serially diluted in 10-fold steps before qPCR was performed. For all PCR amplifications, a 25 µl reaction mixture containing 12.5 µl GoTaq® Green Master Mix (Promega Benelux BV, Leiden, the Netherlands), 10 pmol of primers and 10-20 ng DNA of template DNA was used. PCR products were ligated to pGEM®-T easy vector (Promega Benelux BV, Leiden, the Netherlands) according to the manufacturer’s instructions. Plasmid DNA was extracted...
using GeneJET™ Plasmid Miniprep Kit (Fermentas GMBH, St.Leon-Rot, Germany) and the insert was sequenced by M13 Forward primer (5’, GTAAAACGACGGCCAGT 3’). Phylogenetic trees were constructed using MEGA 5 software (33).

Results

Enrichment of the aerobic ammonium oxidizing bacteria

The anammox biomass (~80% enriched) from the sequencing batch reactor (SBR) operated at 30 °C was used as inoculum for the nitritation-anammox SBR. After inoculation, the bioreactor was operated at 25 °C and anaerobically for two weeks with 420 mg-N/l nitrite (30mM) and 588 mg-N/l (42 mM) ammonium as substrates in the influent (flow rate: 1.8 l/d). Within this period, anammox bacteria were responsible for all ammonium and nitrite consumption. To enrich an anammox-AOB coculture, O2 was supplied to the reactor continuously after day 14. To avoid the inhibition of anammox bacteria, O2 was supplied in such a way that it was always below detection limit (0.05 mg O2/l) due to the activity of AOB. At day 34, *Nitrosomonas*-like microorganisms were detected by FISH and aerobic ammonium oxidizing activity was detectable indicating that an AOB community had already developed within 20 days. On day 119 the concentration of ammonium was decreased to 210 mg-N/l (15 mM) and nitrite was no longer supplied to the reactor. After this point, the nitrite required for anammox reaction was completely produced by the AOB. To mimic pre-treated municipal nitrogenous wastewater, ammonium concentration was lowered to 70 mg-N/l (5 mM)
on day 191 (Figure 1) and was kept at this value for the rest of the experimental period. Ammonium supplied to the nitritation-anammox SBR was partially oxidized by AOB to nitrite, which was consumed by the anammox bacteria subsequently together with the remaining ammonium. Within just 10 days (between days 125 and 136), the temperature of the reactor could be gradually lowered from 25 °C to 12 °C without nitrite accumulation. On day 150, the temperature of the reactor was lowered to 9 °C, which resulted in a gradual nitrite accumulation (up to 14 mg-N/l). Increasing the temperature back to 12 °C on day 152 alleviated this accumulation.

Changes of community composition in response to temperature and oxygen

The results of FISH analysis of the biomass from the nitritation-anammox SBR showed a clear increase of AOB abundance after the air supply started. At day 20, one week after the start of O2 additions, still only anammox bacteria could be detected by FISH (Figure S1), the abundance of AOB was apparently below detection limit (10000 cells/ml, <1% of the microbial population). With increasing O2 supply, the abundance of AOB increased to about 50% of the total population (Day 135, Figure S1) and anammox bacteria and AOB comprised approximately 90% of the population as detected by DAPI (data not shown). Clone libraries (Figure S2) and FISH analyses revealed that after the introduction of oxygen, the dominant anammox species in the bioreactor was a “Candidatus Brocadia fulgida”-like strain and it did not change throughout the operation of the nitritation-anammox SBR. It was not possible to detect NOB with the most general probes during the experimental period.

Functional gene abundance of anammox and AOB

10
Anammox bacteria and AOB in the nitritation-anammox SBR were quantified by real-time qPCR performed on hzsA and amoA genes, respectively. At day 35, 20 days after the introduction of oxygen and when the temperature was 25 °C copy numbers of hzsA and amoA genes were ~ 7×10⁹ per ml and ~ 4×10⁷ per ml, respectively indicating that the AOB started to grow in the bioreactor albeit their population only comprised ~1% of the total population. The anammox copy numbers corresponded to an in situ anammox activity of 10 f mol N·cell⁻¹·d⁻¹. An increase in amoA gene copy numbers was observed subsequently, which was congruent with the FISH results. At day 353, after more than 200 days extended enrichment at 12 °C, the copy number of hzsA and amoA genes were ~ 2×10⁷ copies·ml⁻¹ and ~ 8.6×10⁶ copies·ml⁻¹, respectively. At this stage the in situ anammox and AOB activities were 10.5 and 24 f mol N·cell⁻¹·d⁻¹, respectively.

The effect of temperature and oxygen on activities of different trophic groups

In the 100 days after the introduction of O₂, there was a decrease in the observed anammox activity from 16.6 to 12 nmol N·mg total protein⁻¹·min⁻¹ in the nitritation-anammox SBR. This decrease was most probably due to the fact that the AOB were growing in the total biomass and consuming part of the ammonium. AOB activity doubled with increasing O₂, and stabilized at around ~27 nmol N·mg total protein⁻¹·min⁻¹ at 12 °C. NOB activity was undetectable during the whole experimental period, which indicated that all substrates were consumed by anammox and AOB.

When the nitritation-anammox SBR was operated at 12 °C for 120 days, anammox activity increased from 12 to about 18 nmol N·mg total protein⁻¹·min⁻¹, which indicated
a successful adaptation to low temperature (Table 1). To investigate the effect of temperature on anammox activity, biomass from the 12 °C nitritation-anammox SBR and the anammox SBR were sampled and incubated at different temperatures. The optimum temperature for the anammox biomass from the nitritation-anammox SBR enriched at 12 °C was 25 °C, 10 °C lower than the biomass originating from the anammox SBR operated at 30 °C. Interestingly, the maximum specific activity (activity per anammox protein) of anammox bacteria grown at 30°C and 12 °C were almost identical (Figure 2). Moreover, cold adapted biomass still oxidized ammonium at a rate of 5 nmol N mg protein⁻¹ min⁻¹ at 12 °C (Figure 2), which was high enough to remove all nitrogen supplied to the system. The AOB from the cold adapted reactor had the maximum specific activity (activity per AOB protein) at 25 °C and an activity of 10 nmol N mg protein⁻¹ min⁻¹ at 12 °C.

Anammox bacteria oxidize a part of their substrate nitrite not nitrate for reducing equivalents necessary for cell carbon fixation; therefore, when anammox bacteria are growing, nitrate production is observed. With the decreasing temperature, there was also a decrease in nitrate production by anammox bacteria in the nitritation-anammox SBR. In the 68 days before the temperature was lowered, the average ratio of nitrate produced to ammonium consumed by the anammox bacteria was approximately 0.18, which is similar to the stoichiometric value of 0.26. Conversely in the last 158 days when the reactor was operated at 12 °C this ratio decreased to 0.04 suggesting that the anammox bacteria had a lower yield and/or higher maintenance activity.

As measured by three grab samples measured in triplicate, N₂O emission from the
nitritation-anammox SBR at 12 °C was ~ 2.4% (± 0.1 %) of total N-removed (Figure 3).

Discussion

In this study, first the temperature of the bioreactor of an existing anammox culture was lowered from 30 to 25 °C within one day without adverse effects indicating that the anammox bacteria had a sufficient overcapacity. Then, a coculture of aerobic ammonium oxidizing bacteria (AOB) and anammox bacteria was enriched in the same reactor by introducing a limiting amount of oxygen to the bioreactor. After establishing a stable co-culture consisting of equal amounts of anammox bacteria and AOB (day 127), the temperature of the nitritation-anammox SBR was decreased from 25 to 12 °C. It was possible to decrease the temperature of the bioreactor within 10 days without nitrite accumulation and this decrease did not result in a change in the dominant anammox species in the bioreactor. Conversely, when the temperature of the reactor was lowered to 9 °C, there was a gradual (from day 150 to 152) nitrite accumulation up to ~ 6 mg-N/l. Increasing the temperature back to 12 °C resulted in the consumption of the accumulated nitrite. This indicates that even though it was not possible to achieve complete nitrite conversion at 9 °C, the decrease in activity was reversible. Such a nitrite accumulation could be because AOB have a higher activity than anammox bacteria at 9 °C (Figure 2). Nevertheless, it cannot currently be ruled out that with a slower decrease of temperature or by using a different type of biomass (e.g. granular) complete nitrite conversion could be reached at temperatures lower than 12 °C. Considering the long doubling time of anammox bacteria (10-25 days) (34), the
acclimation period was very short, indicating that sludge from full-scale bioreactors operating at 30°C could be used to seed new bioreactors designed to remove nitrogen from pretreated low-temperature municipal wastewaters without an extended adaptation period.

Growth of the anammox bacteria is always associated with nitrate production because these microorganisms oxidize part of the nitrite to nitrate as the ultimate source for the electrons that are used for cell carbon fixation. The stoichiometric ratio of nitrate production to ammonium consumption for the anammox bacteria is 1:0.26. When the temperature of the nitritation-anammox SBR was decreased from 25°C to 12 °C this ratio decreased from 0.18 (average of the first 68 days) to 0.04 (the average of the last 158 days) indicating that the anammox bacteria had a lower yield and/or much higher cell maintenance activity at lower temperature. This phenomenon could be the reason why the decrease in temperature resulted in a 100-fold decrease in the copy numbers of the anammox bacteria. Nevertheless, the decrease in temperature did not have an adverse effect on the maximum potential and in situ activity rates of aerobic and anaerobic ammonium oxidizing bacteria in the nitritation-anammox SBR (Table 1) suggesting that these groups of microorganisms had an overcapacity for the conversion of their substrates. The in situ activities of both groups of microorganisms in the nitritation-anammox SBR, albeit they were 30% of the maximum (as measured in batch tests), were sufficient to remove more than 90 % (92 %, average of the last 100 days) of the supplied ammonium indicating that the full-scale application of nitritation-anammox reactors at low temperature and low ammonium concentration
there was a clear optimum temperature shift (35 to 25 °C) in the activity of the cold
adapted anammox biomass from the nitritation-anammox SBR and it was still active
at a wide temperature range (10 - 35 °C). This indicated that the activity loss caused
by low temperature was reversible and the common seasonal changes in temperature
at full-scale application would not affect the stability of the treatment system.
Currently, nitritation-anammox reactors are operated at temperatures higher than
30 °C (10, 11) and previous studies on the physiology of the anammox bacteria
reported that the optimum growth temperature for anammox bacteria is around
30-35 °C (see Jetten et al., 2001 for a review) (35). Moreover, most described AOB
have an optimal temperature of around 28 °C (36). On the other hand, some studies
indicated that nitrite oxidizing bacteria were capable to grow at lower temperatures
varying from -2 °C (37) to 17 °C (36) and that at 10°C to 15°C, NOB had a higher
activity than AOB (15). If NOB had a competitive advantage over AOB or anammox
bacteria below 20-25 °C, depending on their affinity for nitrite and O₂, they could take
up the limiting O₂ and nitrite before AOB and anammox bacteria, respectively. In turn,
this would lead to nitrate production and eventually the collapse of the system.
Nevertheless, in the natural ecosystems where aerobic and anaerobic ammonium
oxidizing bacteria thrive (for example oxygen minimum zones), the temperature is well
below 10 °C indicating that both clades of microorganisms are able to compete with (or
outcompete) NOB (38, 39). This was also the case in our nitritation-anammox
enrichment culture under oxygen limitation: NOB activity could not be detected
throughout the operation of the reactor (Table 1, Figure S1). Even an extended enrichment at 12°C (132 days) did not facilitate the growth of NOB. Our results showed that anammox bacteria directly consumed nitrite produced by AOB and when the system was both nitrite and O₂ limited, NOB had a lower affinity to nitrite than anammox bacteria (40, 41). In our laboratory-scale bioreactor, nitrite oxidation activity could easily be suppressed under oxygen limitation and did not contribute to nitrate formation. Nevertheless, balancing aeration with varying ammonium loading could prove difficult to achieve in full-scale applications. Therefore a thorough study at pilot scale would be necessary to determine the optimal process conditions and control parameters that would lead to a stable full-scale operation.

Dissolved O₂ concentration is also one of the parameters influencing the emission of N₂O from nitritation-anammox bioreactors, most of which is attributed to the activity of AOB (42-45). Our results were completely in line with this observation: there was a negligible (0.02%) amount of N₂O produced in the anammox SBR (80% enriched) operated at 15 °C. On the other hand, in the nitritation-anammox SBR, ~ 2.4% of removed nitrogen was detected as N₂O (Figure 3). This value was remarkably similar to the N₂O production from full-scale nitritation anammox bioreactors (~2.6% of removed nitrogen). Nevertheless, it should be noted that the laboratory scale nitritation-anammox bioreactor in this study was operated under controlled and stable conditions. On the other hand, in full-scale application, many parameters, including wastewater quality, efficiency of the previous treatment steps and temperature fluctuate and the results obtained here cannot be used to directly estimate N₂O emissions from
In this study we present the proof of principle for the application of the nitritation-anammox process for nitrogen removal from pretreated municipal wastewater. It was possible to adapt a nitritation-anammox bioreactor to low temperature and low ammonium load very rapidly. Moreover, the lab scale nitritation-anammox bioreactor was operated for over 300 days without nitrite accumulation and was able to remove over 90% of the supplied nitrogen at temperatures as low as 12 °C. Nevertheless, further studies are necessary to be able to determine the feasibility of the application of such a process at full-scale. We believe that these should focus especially on determining process control parameters for the optimal operation of nitritation-anammox bioreactors under variable wastewater conditions and the degree of greenhouse gas emissions (e.g. N₂O) from these systems.
