Received 11 November 2005/Accepted 19 January 2006

Pharmaceuticals, culture media used for in vitro diagnostics and research, human body fluids, and environments can retain very low ethanol concentrations (VLEC) (≤ 0.1%, vol/vol). In contrast to the well-established effects of elevated ethanol concentrations on bacteria, little is known about the consequences of exposure to VLEC. We supplemented growth media for Staphylococcus aureus strain DSM20231 with VLEC (VLEC conditions) and determined ultramorphology, growth, and viability compared to those with unsupplemented media (VLEC conditions) for prolonged culture times (up to 8 days). VLEC-grown late-stationary-phase S. aureus displayed extensive alterations of cell integrity as shown by scanning electron microscopy. Surprisingly, while ethanol in the medium was completely metabolized during exponential phase, a profound delay of S. aureus post-stationary-phase recovery (> 48 h) was observed. Concomitantly, under VLEC conditions, the concentration of acetate in the culture medium remained elevated while that of ammonia was reduced, contributing to an acidic culture medium and suggesting decreased amino acid catabolism. Interestingly, amino acid depletion was not uniformly affected: under VLEC conditions, glutamic acid, ornithine, and proline remained in the culture medium while the uptake of other amino acids was not affected. Supplementation with arginine, but not with other amino acids, was able to restore post-stationary-phase growth and viability. Taken together, these data demonstrate that VLEC have profound effects on the recovery of S. aureus even after ethanol depletion and delay the transition from primary to secondary metabolite catabolism. These data also suggest that the concentration of ethanol needed for bacteriostatic control of S. aureus is lower than that previously reported.

Staphylococcus aureus is an opportunistic human pathogen (27) causing significant morbidity and mortality in both community-acquired and nosocomial infections. Examples of clinical disease include infective endocarditis, osteomyelitis, and infections associated with the use of medical devices such as catheters and implants (16, 26). S. aureus is a highly versatile organism capable of surviving under untoward environmental conditions (5), thus representing a major challenge in infection control (20).

In medicine, alcoholic compounds have numerous applications as stabilizers, solvents, and disinfectants. A large variety of therapeutics (typically liquids for oral application, e.g., cough suppressants, expectorants, oral tranquilizer suspensions) contain ethanol at various concentrations. Furthermore, a number of pharmaceuticals for intravenous treatment also contain ethanol at concentrations ranging from 1% (vol/vol) to 96% (vol/vol). Most alcohol-based disinfectants contain ethanol, typically at a concentration of ~ 70 to 85% (vol/vol). As an example, antibiotic lock therapy of implanted intravenous catheters uses alcohol as an antimicrobial disinfectant (9) and is widely applied, particularly in pediatrics (34). Finally, ethanol may also be used for food preservation (35). Given the large range of ethanol concentrations in the different preparations, and considering washout, dilution, and evaporation, the actual concentrations in situ are anticipated to be more diverse and would include very low ethanol concentrations (VLEC); hence, a fundamental understanding of the effects of VLEC on bacterial physiology is important.

In addition to the above applications, ethanol or related alcohols are routinely used in medical microbiology for in vitro testing as a solvent: According to CLSI (formerly NCCLS) guidelines (30), 95% ethanol or methanol is recommended to dissolve various macrolides, chloramphenicol, and rifampin. The final concentration of ethanol in the medium depends on the concentration of the antimicrobial selected; for instance, a solution containing 10 μg/ml of the respective antimicrobial also contains 0.1% (vol/vol) ethanol. Furthermore, bacterial genetic research employing erythromycin resistance as a marker for selection typically employs final concentrations of 10 μg/ml erythromycin, i.e., a solution containing 0.1% (vol/vol) ethanol.

The bactericidal activity of ethanol is due to several factors: disruption of membrane structure or function (1, 12, 15, 36); interference with cell division, affecting steady-state growth (12); variations in fatty acid composition and protein synthesis (8); inhibition of nutrient transport via membrane-bound...
ATPases (4); alteration of membrane pH (4, 40) and membrane potential (ΔΨ) (40); and a decrease in intracellular pH (4, 18, 40). In a recent study with the gram-positive organism Bacillus subtilis, it was demonstrated that treatment with sub-inhibitory concentrations of ethanol (not affecting vegetative growth) inhibited the initiation of spore development through a selective blockage of key developmental genes under the control of the master transcription factor Spo0A–P (14). These toxic effects have been described for a wide variety of microbial species, and for use of different concentrations of ethanol, ranging from 2.5% to 70% (1, 2, 8, 10, 19, 25, 36). Surprisingly, very little is known about the physiological effects of VLEC. Therefore, the purpose of this study was to determine the effects of VLEC on medically important staphylococci at a concentration frequently encountered in the hospital and laboratory. In this study, we report major effects of VLEC on S. aureus cell integrity, survival, and growth recovery, and we describe the effects of VLEC on metabolism and transcription of select staphylococcal genes.

(Materials and methods)

Bacterial strains and growth conditions. Staphylococcus aureus DSM20231 (37) (from the Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH, Braunschweig, Germany) (ATCC 12600; Cowan serotype 3) was used throughout this study. In select experiments, S. aureus strain SH1000 was used (17). Strains were grown in brain heart infusion (BHI; Oxoid) medium or on Mueller-Hinton medium containing 1.5% agar. All bacterial cultures were inoculated from an overnight culture and diluted to an optical density at 600 nm (OD600) of 0.1 into BHI incubated at 37°C. For generation of microaerobic conditions were designated “VLEC positive” (VLEC+). In the following text, these descriptions are used throughout this study. In select experiments, S. aureus grown in brain heart infusion medium (BHI; Oxoid) with bacteria or without bacteria (n = 2 each), 0.1 ml of sample was taken at time zero and at 2, 4, 7, and 24 h. The samples were analyzed by headspace gas chromatography (80°C; column, 0.1% SP-1000/Carboxen 50/50 [HP 88] and flame ionization detection for ethanol quantification or mass selective detection for identification of ethanol and acetaldehyde (29).

Gas chromatography. From the incubation culture (brain heart infusion medium with 0.1% ethanol) with bacteria or without bacteria (n = 2 each), 0.1 ml of sample was taken at time zero and at 2, 4, 7, and 24 h. The samples were analyzed by headspace gas chromatography (80°C; column, 0.1% SP-1000/Carboxen 50/50 [HP 88] and flame ionization detection for ethanol quantification or mass selective detection for identification of ethanol and acetaldehyde (29).

Determination of stationary-phase survival. Single colonies of S. aureus strains were inoculated into 100-ml flasks containing 50 ml of BHI (unsupplemented or supplemented with ethanol), grown at 37°C, and aerated by shaking at 150 rpm for up to 9 days. Aliquots (200 μl) were harvested at 24-h intervals, and the CFU was determined.

Scanning electron microscopy. Bacterial cells were harvested at different time points (24 h, 48 h, 72 h, 120 h, and 192 h). The pellet was resuspended in a mixture of 1% formaldehyde–1% glutaraldehyde–0.1% picric acid in 0.1 M phosphate buffer (pH 7.2) at room temperature and then stored at 4°C. All formaldehyde solutions were prepared from freshly depolymerized paraformaldehyde. Cell pellets were washed with phosphate buffer and then prepared for scanning electron microscopy. A dense suspension of washed cells was filtered on grids. Cells were dehydrated by use of an ethanol gradient and then subjected to critical-point drying. Subsequently, samples were mounted on aluminum sample holders and sputter coated with platinum, then inspected with an ESEM XL 30 (FEI, The Netherlands) scanning electron microscope at 20 to 30 kV.

Results

Electron microscopy analysis of S. aureus cells grown in the presence of ethanol under microaerobic conditions. High concentrations of ethanol are bactericidal; however, bacteria can grow in the presence of low concentrations of ethanol (21, 22). These observations led us to question whether morphological changes would be induced upon growth of S. aureus under such conditions. Thus, we examined S. aureus grown under VLEC+ conditions by using scanning electron microscopy at different time points throughout the growth cycle (Fig. 1). No morphological differences were observed (Fig. 1A, F, and K) until between 48 h and 192 h postinoculation, when striking changes could be seen in S. aureus grown in a VLEC+ medium (Fig. 1G to J). The presence of collapsed and broken cells, cell debris, and indentation of the cell surface in these cells suggested the
FIG. 1. Effects of VLEC and arginine on micromorphology of *S. aureus* DSM20231. Shown are representative scanning electron micrographs of *S. aureus* DSM20231 grown for various times (24 h, 48 h, 72 h, 120 h, and 192 h) in unsupplemented medium (A to E, top to bottom), under VLEC$^+$ conditions (F to J, top to bottom), or under VLEC$^+$ conditions and supplemented with 5 mM arginine (K to O, top to bottom).
possibility of a weakened cell wall. In contrast, cells grown in the absence of ethanol had more intact cells and a normal smooth, spherical appearance (Fig. 1A to E). Interestingly, the effects of ethanol occur only when the bacterial cultures are grown under microaerobic conditions. Taken together, these data suggest that the effect of VLEC on the growth and/or viability of *S. aureus* is delayed.

**Ethanol delays post-stationary-phase recovery.** VLEC did not alter the exponential growth rate (Fig. 2A and B); however, it slightly decreased the growth yield (24 h). Between 48 h and 72 h in culture, the cell density for bacteria grown in the absence of ethanol increased, suggesting post-stationary-phase growth. In contrast, bacteria grown under VLEC+ conditions lysed between 24 to 48 h, reaching a nadir in cell density (Fig. 2C).
2A) and CFU (Fig. 2B) at 96 h and increasing in cell density after 120 h. These findings were consistent with the morphological observations (Fig. 1). The effect of ethanol on the late stationary phase was dependent on the ethanol concentration (Fig. 2C). Post-stationary-phase growth was delayed at concentrations between 0.075% (vol/vol) and 0.1% (vol/vol), while at more elevated concentrations post-stationary-phase growth was inhibited, and exponential growth (at 24 h) was also affected. In contrast, a concentration of 0.05% (vol/vol) ethanol showed post-stationary-phase growth characteristics indistinguishable from that under VLEC<sup>c</sup> conditions. <i>S. aureus</i> grown in unsupplemented medium entered the final death phase (defined as the loss of viable counts without a concomitant reduction in optical density) immediately after the post-stationary growth phase (at 96 to 120 h) (5 to 6 days). In contrast, VLEC-treated <i>S. aureus</i> entered the final death phase much later (168 h). To determine if these results were due to strain-specific factors, an identical experiment was performed using strain <i>S. aureus</i> SH1000. The effect of VLEC on strain SH1000 was nearly identical to that on strain DSM20231 (data not shown), suggesting that the response of strain DSM20231 to VLEC is common to <i>S. aureus</i> strains of different genetic backgrounds.

A possible explanation for the delayed post-stationary-phase recovery in the VLEC<sup>c</sup> population is the emergence of escape mutants with reduced susceptibility to ethanol. To test this
hypothesis, we performed an ethanol susceptibility assay on late-stationary-phase bacteria. VLEC-grown staphylococci (both DSM20231 and SH1000 strains) were grown for 12 h, from post-stationary phase (120 h), in media containing various concentrations of ethanol (0%, 1%, 5%, 10%, 25%, and 50%). These bacteria were just as sensitive to ethanol as bacteria obtained from fresh overnight cultures or organisms grown under VLEC/H11002 conditions (data not shown). A second possible explanation for the prolonged recovery time of VLEC-treated bacteria might be inefficient membrane repair. To address this possibility, we determined the membrane potential of *S. aureus* in the presence of VLEC (Fig. 2D). We were unable to detect any difference in membrane potential in *S. aureus* DSM20231 after addition of 0.1% ethanol relative to the untreated control. Taken together, these data suggest that VLEC does not facilitate the generation of escape mutants or significantly alter the membrane potential.

**Ethanol is rapidly removed from the culture medium.** Ethanol is a volatile organic alcohol (flash point, 13°C); thus, it was surprising that the effects of VLEC on post-stationary-phase recovery persisted until 120 h (5 days) into the growth cycle. We speculated that ethanol would be lost due to evaporation and/or catabolism well before 120 h; hence, we determined the concentration of ethanol in the culture medium throughout the growth cycle. As expected, the concentration of ethanol in the culture medium began to decrease immediately after inoculation, and by 24 h no ethanol remained (Fig. 3A). To assess if ethanol evaporated or was enzymatically catabolized, VLEC/H11001 supernatants were examined by gas chromatography at various time points after supplementation with ethanol both in the presence and in the absence of *S. aureus* (Fig. 3B). In the absence of microorganisms, the concentration of ethanol in the medium remained stable over 24 h, while in the presence of *S. aureus* ethanol was depleted from the culture medium by 24 h, suggesting that the bacteria were catabolizing the ethanol. Concomitantly, under VLEC(H11001) conditions, transcription of *adhE* (the alcohol-acetaldehyde dehydrogenase gene) was elevated earlier (at 3.5 h) than under VLEC(H11002) conditions, indicating a contribution of alcohol dehydrogenase to ethanol catabolization (Fig. 3C). Most importantly, these data demonstrate that the effects of

**FIG. 4.** Analysis of external pH and levels of metabolites of the culture supernatant. External pH (A) and levels of glucose (B), acetate (C), and ammonia (D) in the culture supernatant of *S. aureus* DSM20231 were determined under VLEC(H11002) (■) and VLEC(H11001) (●) conditions at the indicated time points. Data are representative of two independent experiments.
FIG. 5. Depletion of free amino acids from the BHI medium. Shown are concentrations of free amino acids L-serine (A), L-glycine (B), L-arginine (C), L-glutamic acid (D), L-ornithine (E), and L-proline (F) in BHI culture medium of *S. aureus* DSM20231 grown under VLEC/H11002 (□) and VLEC/H11001 (●) conditions. Data are mean molar concentrations (nmol/ml) ± standard deviations of two independent experiments.
VLEC on late-stationary-phase growth and survival persist long after ethanol has been depleted from the culture medium, and they suggest that recovery from ethanol-induced alteration is a delayed process.

**Ethanol delays acetate catabolism and ammonia accumulation.** In VLEC+ cultures, the onset of post-stationary-phase growth was delayed, suggesting that VLEC impaired the metabolism of nonpreferred carbon sources. To determine if VLEC affects metabolism, DSM20231 was grown in VLEC+ medium, and the pH was measured; pH is an indicator of organic acid production. During the first 10 h of incubation, the pHs of the culture medium were nearly identical, irrespective of the presence of ethanol (Fig. 4A). In the absence of ethanol, the pH of the culture medium began to increase at 24 h postinoculation, and by 192 h (8 days), it was alkaline (pH 9.1). In contrast, under VLEC+ conditions, the pH values remained acidic (pH 5.5) until nearly 120 h (5 days). An ethanol-induced inhibition of medium alkalinization can be caused by either a decreased catabolism of organic acids and/or a decreased accumulation of ammonia. To determine which of these two possibilities was responsible for the observed pH difference, we measured the concentrations of glucose, acetate, ethanol, lactic acid, and ammonia in the culture medium. During the exponential phase of growth, the catabolism of glucose was unaffected by the presence of ethanol (Fig. 4B). Similarly, VLEC did not affect the accumulation or depletion of lactic acid in the culture medium (maximum lactate concentrations were 5.77 mM in VLEC− medium and 6.8 mM in VLEC+ medium). The accumulation of acetate in the culture medium was also found to be unaffected by VLEC; however, in VLEC-treated cultures, the depletion of acetate was greatly delayed (Fig. 4C). Additionally, VLEC delayed the accumulation of ammonia (Fig. 4D) until after 144 h, coinciding with the onset of acetate catabolism and the recovery of viable counts and cell density.

**Ethanol affects bacterial uptake of specific amino acids from the culture medium.** The accumulation of ammonia in the culture medium is an indication of amino acid catabolism. As stated above, VLEC+ conditions reduced the accumulation of ammonia in the culture medium until after 144 h (Fig. 4D), leading us to hypothesize that low concentrations of ethanol affect amino acid catabolism. To test this hypothesis, the concentrations of select free amino acids in the culture medium were determined during growth under VLEC+ conditions and were compared to respective determinations in VLEC− cultures. Serine, glycine, and arginine were depleted from the growth medium irrespective of the presence of ethanol (Fig. 5A, B, and C). In contrast, glutamic acid, ornithine, and proline (Fig. 5D, E, and F) were depleted from the culture medium only after growth resumed, resulting in the delayed accumulation of ammonia. In contrast to the other amino acids tested, ornithine accumulated in the medium during growth. Staphylococci use an arginine-ornithine antiporter to transport arginine into the cell; hence, ornithine concentrations increase as arginine concentrations decrease. As the availability of carbon and/or nitrogen becomes limited, staphylococci can catabolize ornithine. VLEC+ conditions delayed the catabolism of ornithine relative to VLEC− conditions.

Surprisingly, the difference in amino acid uptake was only detectable during or after the stationary phase of growth after the ethanol was gone (Fig. 3A), while exponential-phase amino acid catabolism was independent of ethanol. Taken together, these data indicate that the effect of low ethanol concentrations can persist long after the ethanol has been consumed.

**Arginine restores post-stationary-phase recovery under VLEC+ conditions.** Amino acid catabolism is an important source of carbon and energy. The selective depletion of amino acids from the culture medium (Fig. 6) led us to speculate that supplementation of the culture medium with a depleted amino acid would restore post-stationary-phase growth. We tested this hypothesis by supplementation of VLEC cultures with single amino acids at a concentration of 2 mM and assessed their growth and viability. Interestingly, only arginine restored the post-stationary-phase recovery and viability (Fig. 6A; also data not shown). The catabolism of arginine usually involves
the arginine deiminase (ADI) pathway. To ascertain if VLEC\textsuperscript{+} conditions resulted in increased transcription of genes of the ADI pathway, we determined the relative concentration of mRNA for the arcA gene (encoding arginine deiminase) by real-time reverse transcription-PCR (RT-PCR) (Fig. 6B). Consistent with our hypothesis, arcA transcript levels were significantly greater at 3.5 h, 8 h, 17 h, and 22 h in staphylococci grown under VLEC\textsuperscript{+} relative to VLEC\textsuperscript{−} conditions.

**DISCUSSION**

Our results indicate that the transition from primary to secondary metabolite catabolism is delayed by VLEC. *S. aureus* preferentially catabolizes glucose for carbon and energy, a process resulting in the accumulation of organic acids in the culture medium (24, 38, 39). Our results are consistent with these observations, as glucose was rapidly consumed and the pH of the culture medium decreased due to the accumulation of lactate and acetate. Notably, the consumption of glucose and the acidification of the culture medium were unaffected during exponential phase under VLEC\textsuperscript{+} conditions; however, VLEC resulted in a delayed transition from glucose catabolism to secondary metabolite catabolism (7, 39). The delayed transition to the catabolism of nonpreferred carbon sources also resulted in decreased amino acid catabolism (Fig. 5). In *S. aureus*, acetate catabolism requires tricarboxylic acid (TCA) cycle activity, but staphylococci lack the glyoxylate shunt. Hence, for every 2 carbons that enter into the TCA cycle as acetyl coenzyme A, 2 carbons are lost during the oxidative decarboxylation reactions. That is to say, if any carbons leave the TCA cycle in the form of biosynthetic intermediates, then those carbons must be replaced for the TCA cycle to continue to function. Staphylococci replace lost carbons through the catabolism of amino acids; hence, a decrease in acetate catabolism results in a decrease in amino acid catabolism.

Additionally, VLEC\textsuperscript{+} conditions selectively inhibited the utilization of amino acids such as glutamate, proline, and ornithine. d-Glutamate is found in the second position of the peptidoglycan stem peptides in virtually all species analyzed thus far (33) and is essential for growth in *Escherichia coli* (28) and *S. aureus* (6, 11, 13). The other “glutamate family” amino acids ornithine and proline can be converted into glutamate: ornithine by the ornithine aminotransferase (SA0818) and the Δ¹-pyrroline-5-carboxylate dehydrogenase (SA2341) and proline by the proline dehydrogenase (SA1585). Thus, the inability to acquire, or synthesize, glutamate under VLEC\textsuperscript{+} conditions may contribute to cell lysis in the presence of ethanol.

Ethanol enhances the ability of staphylococci to form a biofilm (23). Recent transcriptional profiling data on staphylococci growing in biofilms has suggested that the bacteria are growing anaerobically (3, 32, 42). Consistent with that suggestion, these studies noted increased expression of the anaerobic alternative energy-generating ADI pathway (3, 32, 42). The ADI pathway is composed of three enzymes, arginine deimnase (*arcA*), ornithine transcarbamoylase (*arcB*), and carbamoyl kinase (*arcC*). Together, these enzymes convert arginine to ornithine, ammonia, and carbon dioxide, yielding 1 mol of ATP per mol of arginine consumed. Our data demonstrate that ethanol up-regulates expression of the ADI pathway, leading us to speculate that ethanol enhances biofilm formation, in part, through an alteration of the metabolic flux toward the ADI pathway.

In conclusion, to our knowledge this is the first report demonstrating the effects of VLEC on *S. aureus* growth, viability, metabolism, and cell wall morphology. These effects of VLEC were evident only after the complete depletion of ethanol from the culture medium, suggesting that bacterial recovery from, and adaptation to, ethanol stress is a prolonged process. These observations are incongruent with a prevailing dogma, i.e., that bacteria rapidly adapt or die when exposed to disinfectants, and they open new perspectives in our understanding of bacterial senescence in the presence of subinhibitory concentrations of antiseptic agents.

**ACKNOWLEDGMENTS**

This work has received grant support from the Deutsche Forschungsgemeinschaft (Specialized Priority Programme 1047 and 1130, to M.H.) and in part by a grant from the Medical Faculty of the University of Saarland (HOMFOR, 2004, to M.H.). This paper is number 14628 in the University of Nebraska Agriculture Research Division journal series.

We are indebted to M. Laue, N. Pütz, C. Schröder, M. Josten, and E. Hilgert for technical help in part of the experiments, to S. Foster (Sheffield, United Kingdom) for *S. aureus* strain SH1000, and to H. Labischinski, J. Gehrke, and M. Haber for helpful suggestions and discussions.
